

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

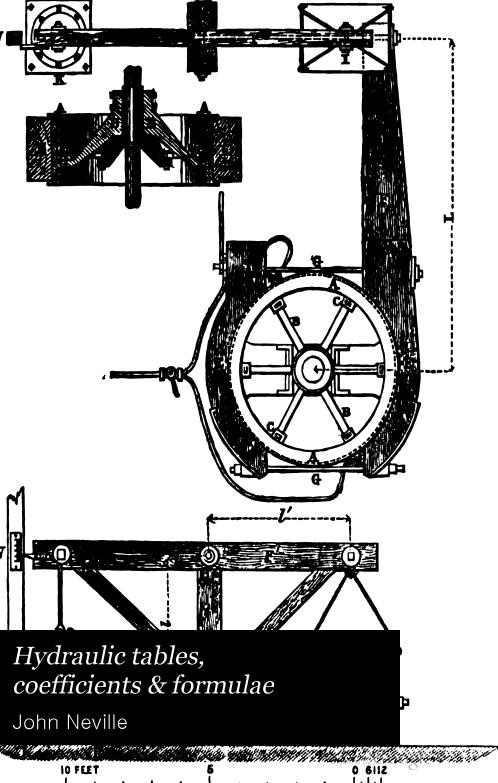

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

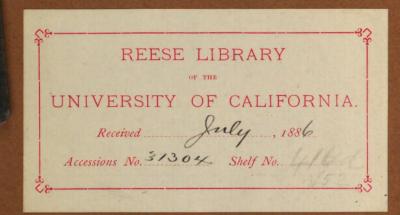

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + Refrain from automated querying Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at http://books.google.com/

HYDRAULIC

TABLES, COEFFICIENTS, AND FORMULÆ,

FOR

FINDING THE DISCHARGE OF WATER FROM ORIFICES, NOTCHES, WEIRS, PIPES, AND RIVERS.

BY

JOHN NEVILLE, CIVIL ENGINEER, M.R.I.A.,

Second Edition:

WITH EXTENSIVE ADDITIONS, NEW FORMULÆ, TABLES, AND GENERAL INFORMATION ON RAIN-FALL CATCHMENT-BASINS, DRAINAGE, SEWERAGE,
'WATER SUPPLY FOR TOWNS AND MILL POWER.

"It ought to be more generally known, that theory is nothing more than the conclusions of reason from numerous and accurately observed phenomena, and the deductions of the laws which connect causes with effects; that practice is the application of those general truths and principles to the common affairs and purposes of life; and that science is the recorded experience and discoveries of mankind, or, as it has been well defined, 'the knowledge of many, orderly and methodically digested, and arranged, so as to become attainable by one."—AMERICAN QUARTERIX BELLER.

AUTHOR.

CONTENTS.

Introduction to the Second Edition	Pages V. to XII.
Introduction to the First Edition	1 to 14
SECTION I. Application and Use of the Tables, Formulæ, &c.—Extra Horse-power required in Pumping Engines from Friction in the Pipes—Table of Heads due to Friction and of Discharges	1548
SECTION II. Formulæ for the Velocity and Discharge from Orifices, Weirs, and Notches—Coefficients of Velocity, Contraction, and Discharge—Practical Remarks on the Use of the Formulæ	4468
SECTION III. Experimental Results and Formula-Co- efficients of Discharge for Orifices, Notches, and Weirs	6395
SECTION IV. Variations in the Coefficients from the Position of the Orifice—General and Partial Contraction—Velocity of Approach—Various Practical Formulæ for the Discharge over Weirs and Notches—Central and Mean Velocities	96—139
SECTION V. Submerged Orifices and Weirs—Contracted River Channels	140—150
SECTION VI. Short Tubes, Mouth-pieces, and Approaches —Alteration in the Coefficients from Friction by in- creasing the Length—Coefficients of Discharge for Simple and Compound Short Tubes—Shoots	150—165
SECTION VII. Lateral Contact of the Water and Tube—Atmospheric Pressure—Head measured to the Discharging Orifice—Coefficient of Resistance—Formula for the Discharge from a Short Tube—Diaphragms—Oblique Junctions—Formula for the Time of the Surface sinking a given depth—Lock Chambers	166—181
SECTION VIII. Plow of Water in Uniform Channels— Mean Velocity — Mean Radii and Hydraulic Mean Depths — Border — Train — Hydraulic Inclination — Effects of Friction — Formulæ for calculating the Mean Velocity — Application of the Formulæ and Tables to the Solutions of three useful Problems	189—934

SECTION IX. Best Forms of the Channel—Regimen—Velocity—Equally Discharging Channels	235—253
SECTION X. Effects of Enlargements and Contractions—Backwater Weir Case—Long and Short Weirs	254—271
SECTION XI. Bends and Curves—Branch Pipes—Different Losses of Head—General Equation for finding the Velocity—Hydrostatic and Hydraulic Pressure—Piezometer—Catchment Basins—Rain-fall per annum	271—289
SECTION XII. Rain-fall—Catchment Basins—Discharge into Channels—Discharge from Sewers—Loss from Evaporation, &c.	289—815
SECTION XIII. Water Supply for Towns—Strength of Pipes—Sewerage Estimates and Cost—Thorough Drainage—Arterial Drainage	815—864
Section XIV. Water Power—Dynamometer, or Friction Brake — Overshot, Breast, and Undershot Vertical Wheels—Turbines and Horizontal Wheels—Hydraulic Ram—Water-pressure Engine—Work of Flour Mills .	364—399
TABLES NOT EMBODIED IN THE TEXT	Γ. Pages
TABLE I. Coefficients of Discharge from Square and Dif- ferently proportioned Rectangular Lateral Orifices in Thin Vertical Plates	400401
TABLE II. For finding the Velocities from the Altitudes and the Altitudes from the Velocities	402—411
TABLE III. Square Roots for finding the Effects of the Velocity of Approach, when the Orifice is small in proportion to the Head. Also, for finding the Increase in the Discharge from an Increase of Head. (See pp. 101 and 107.)	412—418
TABLE IV. For finding the discharge through Rectan-	
gular Orifices; in which $n = \frac{h}{d}$. Also, for finding the	
Effects of the Velocity of Approach to Weirs, and the Depression on the Crest. (See pp.101 and 107.).	414—417
TABLE V. Coefficients of Discharge for different Ratios of the Channel to the Orifice	418—423

TABLE VI. The Discharge over Weirs or Notches of One Foot in Length, in Cubic Feet per Minute. (See pp. 100 and 111 to 127.)	424—429
TABLE VII. For finding the Mean Velocity from the Maximum Velocity at the surface, in Mill-races, Streams, and Rivers with Uniform Channels; and the Maximum Velocity from the Mean Velocity. (See p. 184.)	48 0
TABLE VIII. For finding the Mean Velocities of Water flowing in Pipes, Drains, Streams, and Rivers. (See p. 195)	4 81 —44 8
TABLE IX. For finding the Discharge in Cubic Feet, per Minute, when the Diameter of a Pipe or Orifice, and the Velocity of Discharge, are known, and vice versa.	444—445
TABLE X. For finding the Depths on Weirs of different Lengths, the Quantity discharged over each being sup- posed constant. (See p. 271.)	446
TABLE XI. Relative Dimensions of Equally-Discharging Trapezoidal Channels, with Slopes from 0 to 1, up to 2 to 1. (See pp. 249 and 252.)	447
TABLE XII. Discharges from the Primary Channel in the first column of Table XI. (See p. 253.)	448449
Table XIII. The Square Roots of the Fifth Powers of Numbers for finding the Diameter of a Pipe, or Dimensions of a Channel from the Discharge, or the reverse; showing the relative Discharging Powers of Pipes of different Diameters, and of any similar Channels whatever, closed or open. (See pp. 31, 42, 228, &c.)	450
TABLE XIV. English and French Measures	451454
TABLE XV. Weight, Specific Gravity, Ultimate Strength and Elasticity of Various Materials	555

CORRECTION.

For
$$c = \frac{2}{3} c_d \sqrt{2gh_1}$$
 p. 120, line 18, read $c = \frac{2}{3} c_d \sqrt{2g}$.

INTRODUCTION

TO THE SECOND EDITION.

In order to render this edition more valuable to the hydraulic engineer it has been considerably extended by the insertion of several new tables, formulæ, experimental coefficients, examples, and general estimates of cost. It is hoped that the great extent and practical nature of the additions will render this work far more useful than the first in the ever varying requirements of the profession. The six pages on catchment basins, rain-fall, and water power in the first edition have been extended into three new sections of one hundred and ten pages, embodying the subjects of water supply, sewerage discharge, drainage, and the method of determining the useful effect of water employed in turning the various kinds of water wheels. Considerable additions have also been made in Sections I, III, IV, VIII, and IX; the practical formula for gauging by weirs have been extended through twenty-one extra pages of new matter; the portion treating of the conveying powers of pipes and rivers has been also extended by the insertion of new tables at pages 42, 152, 191, 220, and 252, and of several new formulæ, amongst which we believe that at page 215 (119A), will be found, in practice, the simplest and most accurate yet discovered for ranges of velocity varying between one inch and twenty feet per second, and for all descriptions of channels, pipes, and rivers with which the engineer has to deal.

We have noticed at page 95 the erroneous notation of Morin and other engineers in giving only twothirds of the co-efficient of discharge for weirs. This notation assumes that the theoretical discharge from a notch is the same as if all the particles of water had the same velocity as those undermost, which, being too large by one-third, the experimental coefficient has to be reduced in the same proportion. Mr. Blackwell and Mr. Hughes, in this country, lend themselves to this nomenclature; the latter gentleman says, page 328 of his useful treatise on Water Works*, "Mr. Neville, in his tables of the discharge over weirs, termed the theoretical discharge 321h3 instead of $481h^{\frac{3}{2}}$ in cubic feet per minute." We were correct in doing so, for a weir one foot long; and those who adopt the latter formula are in error: this is a matter of demonstration, not of opinion. We can see no reason for sanctioning a different notation for notches, or orifices at the surface, and sunk orifices. The coefficients when in thin plates, with large cisterns, have nearly the same general value, .615 to .628, and it tends to confusion to adopt in one place a coefficient for a correct formula, and in another a coefficient for an incorrect one; although the final result by an equality of contrary errors may be the same in both. We may here observe-

^{*} Weale's Series.

how very general the coefficient of two-thirds, and thereabouts, is for all orifices, notches, and also for the useful effect derived from the application of water power, as well as the relation of the velocity due to the fall and the velocity of water wheels to give a maximum result. The modifications of coefficients dependent on the position, thickness, form, and approaches of an orifice are seldom understood. The defects in the ordinary formula when the velocity of approach has to be considered are pointed out at pages 100, 115, and 116, and it is to be regretted that the authority of D'Aubuisson and others has misled many as to the correct form. Before the effective power of a water wheel, or water engine, can be determined we must know how to gauge the water supplied to it correctly. This can be done only by the application of formulæ varied to suit the circumstances of the case under consideration. From causes, which it is not necessary to enter into here, this has seldom been done, and very little dependence can be placed on results obtained by the formula in common use when applied generally. It is pleasing to follow Francis and Thomson through the steps by which they get the effective power of their wheels, and we have accordingly made considerable use of their labors in Section XIV.

We have modified some of the old partial equations for the velocity in pipes, beginning at (86), from the form $v = \left\{\frac{rs}{b} + \frac{a^2}{4b^2}\right\}^{\frac{1}{2}} - \frac{a}{2b}$, into $v = c\sqrt{rs} - \frac{a}{2b}$; principally for the purpose of giving the numerical values of c in the form $v = c\sqrt{rs}$. Of course these

modifications are only applicable when the value of $\frac{a}{2b}$ is small compared with that of the velocity.

Some remarks will be found at page 224 respecting M. Darcy's new formula for the velocity of water in iron pipes, as given by Morin in his Hydraulique. We have, only since those remarks were written, seen the original Mémoire, printed in Tome XV, Mémoires présentés par divers savants à l'Académie des Sciences de l'Institut Impérial de France, Paris, 1858. This Mémoire extends through 263 quarto pages, of which 34 contain tables calculated from the formula. We have not had time to do more than glance through it, but the deduced formula appears to be entirely derived from the author's experiments. This we consider, to some extent, objectionable; but, however this may be, there can be no doubt that the value of the coefficient c, in the formula $v = c \sqrt{rs}$, increases with the inclination, s, as well as with the diameter, 4r, of the pipe; and as M. Darcy's formula makes the value of the multiplier, c, depend alone on the value of r, or 4r, there appears an omission, in making the coefficient of friction entirely independent of the hydraulic inclination, and dependent only on the size of the channel. We shall give a few examples, taken at discretion, to show how limited this formula must be in its application.

1. Couplet's experiment, No. 43, p. 103, reduced to feet, gives r = .3997 feet, s = .0035, rs = .001339, and the observed velocity v = 3.478 feet $= .95 \sqrt{rs}$ nearly. Darcy's formula would give $v = .110.8 \sqrt{rs}$, our formula $106 \sqrt{rs}$ nearly, and Weisbach's

- 105 \sqrt{rs} nearly. The pipe was probably an old one, and a deduction of about 10 per cent. might be made for the state of the bore. We have here, however, no means of judging the effect of a change of inclination on the multiplier, c.
- 2. From Du Buât's experiments with an inch pipe, nearly, Nos. 50 and 51, p. 103, we get, after reducing them to feet, in experiment 50, r = .0222, s = .228 and v = 6.33 feet = $89.2 \sqrt{rs}$; or, after making the necessary deductions in the head for the velocity and the orifice of entry with the coefficient *815, s = .147 and v = 6.33 feet = 111.4 \sqrt{rs} . In experiment 51, we also get in feet r = 0222, s =3074, and $v = 7.54 = 92 \sqrt{rs}$; or, by making allowance for the head due to the velocity and the orifice of entry, as before, s = 179, and v = 7.54feet = 119.7 \sqrt{rs} . Here we see how the velocity or value of the inclination, s, affects the value of the multiplier, the diameter remaining constant. M. Darcy's formula, in each case, would only make $v = 80.8 \sqrt{rs}$
- 3. In the excerpt proceedings of the Institution of Civil Engineers, p. 4, 6th February, 1855, James Simpson, president, in the chair, there is given for the "Colinton pipe" 16 inches diameter, eight or nine years in use, three observations. First, 29,580 feet long, a head of 420 feet and a discharge of 571 cubic feet per minute: these give v = 6.816 feet = $99.2 \sqrt{rs}$ nearly. Secondly, a length of 25,765 feet a head of 184 feet, and a discharge of 440 cubic feet per minute: these give v = 5.252 feet = $96.3 \sqrt{rs}$. And thirdly, a length of 3,815 feet a head of 184

feet, and a discharge of 1,215 cubic feet per minute: these give v = 14.5 feet $= 115 \sqrt{rs}$ nearly. In these three examples, the diameter, castings, and age of the pipes are the same. Yet we see, clearly, that the inclination affects the multiplier of \sqrt{rs} , which increases with the inclination, s, although M. Darcy's formula would make the multiplier the same in each case, and for all inclinations, viz. $v = 110 \sqrt{rs}$. Making those allowances inseparable from the state of the pipe, and all experimental observations, these results, as well as those from Du Buât's experiments, confirm the accuracy of our general formula (119A) page 215*, and those others we have given following it, as well also as that of Weisbach.

Dr. Young's formula, page 207, bears a resemblance to that of M. Darcy, in making the multiplier of \sqrt{rs} depend only on the diameter; but it works in a contrary manner: for the high velocities being derived from pipes, with small diameters in the experiments at his command, the value of c in $v = c \sqrt{rs}$, reduced from his formula, becomes larger in general for small than for larger diameters. No doubt an allowance should be made in small pipes for a thin film of water adjoining the pipe with little or no velocity; but within the limits which the engineer has to deal this may be neglected. Its effect,

^{*} The form in which we first discovered this formula was $v = \left\{140 - \frac{10 \cdot 6}{(r \, s)^1}\right\} \times \sqrt{r \, s}$. For measures in metres it becomes $v = 77 \cdot 3 \ (r \, s)^2 - 4 \cdot 9 \ (r \, s)^2$; in which r is half the radius of a cylindrical pipe, or the hydraulic mean depth of any channel.

as well as that of all the other resistances, junctions, contractions, deposits, &c., is greater in small than in large pipes. We must refer to the body of the work for further remarks on this subject, but from lately appearing at such length in the Mémoires of the Imperial Academy of Sciences, M. Darcy's formula called for especial notice here.

The Statistics of rain-fall and catchment-basins have not yet received the attention which the subject deserves. The distribution of rain gauges with reference to elevation, contour, temperature, and isothermal lines has not been sufficiently attended to. The connexion of the rain-fall with the discharge generally, for the whole catchment, for the tributary catchments, and their sub-catchments, at the sea in the middle districts and at the sources, noting the geology, must be observed for several years before the questions of supply, discharge, absorption, and evaporation in any climate can be answered. The maximum and minimum discharges in each year and series of years must be observed, as well as the average mean discharges, and the maximums and minimums of these also, before the physical connexion of climate and catchment can be correctly ascertained, and the engineer furnished with reliable data. Heretofore observations, even when best, have been partial or limited, and a wide field is here yet open to competent physicists in connexion with our drainage works.

The general items of cost given in Section XIII. will be found of use; they are intended, however, more as guides than as standards for other

works, the cost of which must depend on their own circumstances. Those who have practical experience of the differences between estimates, cost, and value, and how they are affected by time, locality, quality, and quantity, will estimate for each case in detail; but the discrepancies between estimates and cost, even under the same circumstances, are too well known to call for any remark here.

A few words about our publisher. Mr. Weale having purchased our interest in this edition, at once decided on adopting larger type and better paper, at a heavy extra outlay to himself. We had reason to be satisfied with the manner in which the first edition was brought out, in this, however, he has excelled, and we hope his enterprise will receive a fair return.

Joselyn Street, Dundalk, October, 1860.

INTRODUCTION

TO THE FIRST EDITION.

In preparing the following work, we had three objects in view: first, a collection of useful hydraulic formulæ; secondly, a collection of experimental results, and coefficients; and, thirdly, a collection of useful practical tables, some calculated entirely from the formulæ and experiments, and others for the purpose of rendering the calculations more easy.

The TABLES at the end of the volume are all original, with the exception of TABLE I., which contains the well-known coefficients of Poncelet and LESBROS; but those are newly arranged, the heads reduced to English inches, and the coefficients for heads measured over and back from the orifice. placed side by side, for more ready comparison. The coefficients in the small Tables throughout the work have been all calculated by us from the original experiments; the formulæ have been carefully examined, and the continental ones reduced to English measures—some of them, as will be seen, for the No labour has been spared in preparing first time. the TABLES, and they are all purely hydraulic, though some of them are capable of being otherwise applied. We have filled no gap by the introduction of Tables applicable to other subjects, and in every-day use.

The correction of some of the experimental formulæ, particularly the continental ones, as printed in some English books, cost us some labour. Even Du Buât's well-known formula is frequently misprinted; and in a late hydraulic work, \sqrt{d} —1, one of the factors, is printed \sqrt{d} —1 in every page where it is quoted. It is not always that such mistakes can be avoided, but experimental formulæ are so often copied from one work into another without sufficient examination, that an error of this kind frequently becomes fixed; and when applied to practical purposes erroneous formulæ get the correct ones into disrepute. See note to formula (91).

The Tables of velocities and discharges over weirs and notches have been calculated for a great number of coefficients to meet different circumstances of approach and overfall, and for various heads from 4th of an inch up to 6 feet. Table II. embodies the velocities acquired by falling bodies under the head of "theoretical velocity," and the velocities, suited to various coefficients, for heads up to 40 feet.

The formulæ for calculating the effects of the velocity of approach to orifices and weirs, and the necessary corrections for the ratio of the channel to the orifice, as well as Table V., we believe to be original. They will be found of much value in determining the proper coefficients suited to various ratios. The remarks throughout Section IV. are particularly applicable to the proper use of this Table.

TABLE VII. of surface and mean velocities will be found to vary from those generally in use, and to be much more correct, and better suited for practical

purposes, particularly as applied to finding the mean velocities in rivers.

We have extended TABLE VIII. so as to make it directly available for hydraulic mean depths, from 1sth of an inch to 12 feet, and for various hydraulic inclinations, even up to vertical, for pipes. The fall in rivers seldom exceeds 2 or 3 feet per mile, or the velocity 5 or 6 feet per second. The extension of the Table for great inclinations, and consequently great velocities, was made for purposes of calculation, and to include pipes. It must be understood throughout this TABLE that the velocities are those which continue unchanged for any length of channel, viz., when the resistance of friction is equal to the acceleration of gravity, the moving water and channel being then in train. Several of Du Buât's experiments were made with small vertical pipes. This TABLE is equally applicable to pipes and rivers, and gives directly either the hydraulic inclination, the hydraulic mean depth, or the velocity when any two of them are known.

Hydraulic formulæ have been frequently rendered unnecessarily complex, and unsuited for practical application, by combining them with those of mere mensuration in order to find the discharge. We have therefore given formulæ for finding the mean velocity principally,—unless in a few instances, as in orifices near the surface, where the discharge itself is first necessary to find the mean volocity; this once determined, the calculation of the discharge becomes one of simple mensuration.

We have preferred giving the mean velocity to the

discharge itself in TABLE VIII., because, while an infinite number of channels having the same hydraulic inclination (s) and the same hydraulic mean depth (r)must have the same velocity (v), yet the sectional areas, and consequently the discharges, may vary upwards from $6.2832r^3$, the area of a semicircular channel, to any extent; and the operation of multiplying the area by the mean velocity, to find the discharge, is so very simple that any tabulation for that purpose is unnecessary. Besides this, the banks of rivers, unless artificially protected, remain very seldom at a constant slope, and therefore any TABLES of discharge for particular side slopes are only of use so far as they apply to hypothetical cases. we have seen, in new river cuts, the banks, cut first to a given slope, alter very considerably in a few months; while the necessary regimen between the velocity of the water and the channel was in the course of being established. The velocity suited to the permanency of any proposed river channel, though too often entirely neglected, is the very first element to be considered.

For circular pipes, however, Table IX. gives the discharge in cubic feet per minute when the velocity in inches per second is known, or found from Table VIII., and is calculated for pipes from 4th of an inch up to 12 inches in diameter. Table XII. gives also the discharges in cubic feet per minute from the different equivalent river channels in Table XI.

TABLE X., for finding the heads on weirs of different lengths, TABLE XI., of equally discharging river channels, and TABLE XII., of the actual discharges

from the equivalents in Table XI., will be found of great practical value when new weirs and water-cuts have to be made. Tables XI. and XII. are equally applicable to channels having side slopes, the widths being then the mean or central widths.

When the discharge and fall are known, and the hydraulic mean depth and the dimensions of any channel have to be determined, Problem III., section 8, as illustrated in Example 17, section 1, gives a new and perhaps the most practically useful solution yet published. Tables XI., XII., and XIII. are particularly applicable to this problem.

A uniform notation is preserved throughout the work, so that the different experimental formulæ can be compared without any further reduction. letter h is used in every instance for the head, c for the coefficient, r for the mean radius or hydraulic mean depth, and s for the sine of the hydraulic inclination, unless it be otherwise stated. In order to designate particular values, the primary letters have deponent or initial letters below to explain them. Thus h_t is the head to the top of an orifice, h_b the head at the bottom, h, the head on a weir, h, the head due to friction, c_4 the coefficient of discharge, c_7 the coefficient of velocity, c_o the coefficient of contraction, When the whole head is made up of different elements, such as the portions due to friction, velocity, contractions, bends, &c., it is expressed by the capital letter H.

Some writers and engineers appear to confound the inclination of a pipe, simply so called, or the head divided by the length, with the hydraulic inclination; and consequently have fallen into error in applying such of the known formulæ as take into consideration only the head due to the resistance of friction. When pipes are of considerable length, and the water is supplied from a reservoir at one end, the inclination, found as above, and the hydraulic inclination, may be taken equal to each other without sensible error; but for shorter pipes, of say up to 100 feet long, or even longer, the greater number of formulæ, as Du Buât's and others, do not directly apply; and it is necessary to take into consideration the head due to the orifice of entry, the velocity in the tube, and also to the impulse of supply when there are junctions. These separate elements, and their effects, will be considered in the following pages; but it will be of use to refer here to some late experiments, and the imperfect application of formulæ to them, first premising that a pipe may be horizontal, or even turn upwards, and yet have a considerable hydraulic inclination.

Mr. Provis's valuable experiments* with 1½-inch pipes, from 20 to 100 feet long, have been used in a recent work for the purpose of testing the accuracy of Du Buât's and some other formulæ; but the head divided by the length is assumed to be the hydraulic inclination throughout, and no allowance is made for the head due to the orifice of entry and velocity in the pipe. Of course the writer's conclusions are erroneous. We have shown, Section I., page 30, how very nearly the formulæ and experiments agree.

The formulæ appear to have been also misunder-

^{*} Transactions of the Institution of Civil Engineers, Vol. II., pp. 201—210.

stood by the surveyor who experimented for the General Board of Health; for the inclination of the pipe in itself is assumed to be the hydraulic inclination, and no allowance is made for the head due to the impulse of supply. We quote from the Civil Engineer and Architect's Journal, Vol. XV., page 366, in which it is stated that "the chief results as respect the house drains are thus described in the examination of the surveyor appointed to make the trials."*

"What quantity of water would be discharged through a 3-inch pipe on an inclination of 1 in 120?—Full at the head, it would discharge 100 gallons in three minutes, the pipe being 50 feet in length. This is with stone-ware pipe manufactured at Lambeth. This applies to a pipe receiving water only at the inlet, the water not being higher than the head of the pipe.

"What water was this?—Sewage-water of the full consistency, and it was discharged so completely that the pipe was perfectly clean.

"At the same inclination what would a 4-inch pipe discharge with the same distances?—Twice the amount (that I found from experiment); or, in other words, 100 gallons would be discharged in half the time. This likewise applies to a pipe receiving water only at the inlet, and of not greater height than the head. In these cases the section of the stream is diminished at the outlet to about half the area of the pipe.

"Before these experiments were made, were there not various hypothetical formulæ† proposed for general use?—Yes.

[†] It is a mistake to call those formulæ hypothetical, unless so far as the hypothesis is founded on facts. Every formula with which we are acquainted is founded on experiments, and has been deduced from them, but those formulæ are too often hypothetically applied to short tubes without the necessary corrections. It will be seen from Section VIII. that the experiments from

^{*} Minutes of Information with reference to Works for the removal of Soil, Water, or Drainage, &c., &c. Presented to both Houses of Parliament, 1852.

"What would these formulæ have given with a 3-inch pipe, and at an inclination of 1 in 100? and what was the result of your experiments with the 3-inch pipe?—The formulæ would give 7 cubic feet, the actual experiment gave 11½ cubic feet; converting it into time, the discharge, according to the formulæ, compared with the discharge found by actual practice, would be as 2 to 3.

"How would it be with a 4-inch pipe?—The formulæ would give about 14.7 cubic feet per minute, whereas practice gave 28 cubic feet per minute.

"Take the case of a 6-inch pipe of the same inclination?—The results, according to Mr. Hawkesley's formula, would be 40½ cubic feet per minute; from experiment it was found to be 63½ cubic feet per minute.

"Then with respect to mains and drainage over a flat surface, the result of course becomes of much more value, as the difference proved by actual practice increases with the diminution of the inclination?—Certainly, to a very great extent. For example, the tables give only 14.2 cubic feet per minute as the discharge from a pipe 6 inches diameter, with a fall of 1 in 800; practice shows that, under the same conditions, 47.2 cubic feet will be discharged.

"Will you give an example of the practical value of this when it is required to carry out drainage works over a very flat surface?—An inclination of 1 in 800 gives only 14 cubic feet per minute, according to theory, while, according to actual experiment, and with the same inclination, 47 cubic feet are given.

"Then this difference may be converted either into a saving of water to effect the same object, or into power of water to remove feculent matter from beneath the site of any houses or town?

—It may be so.

"And also the power of small inclinations properly managed?—Yes; for example, if it was required to construct a water course that should discharge, say 200 feet per minute, the formula would require an inclination of 1 in 60=2 inches in 10 feet; whereas, experiment has shown that the same would be discharged at an inclination of 1 in 200=\(\frac{4}{3} \) inch in 10 feet, thus effecting a considerable saving in excavation, or a smaller drain would suffice at the greater inclination."

which the formulæ there given were derived, were in every way greatly more extensive than those made by the directions of the Board of Health. The formula named is, substantially, Eytelwein's algebraically transformed.

We have extracted and tabulated the results given above, in the following Table, and also eight of the experiments made for the Metropolitan Commissioners of Sewers*; and assuming for the present, with the surveyor, examined by the Commissioners, that the inclinations of the pipes and hydraulic inclinations of the formulæ are the same, which is incorrect, we give the calculated discharges, found by means of Tables VIII. and IX., in the last column of the Table.

Diameter of pipe in inches.	Inclination of pipe.	Discharge in cubic feet per minute by experiment.	Hypothetical discharge by Du Buât's formula.
8	1 in 120	5.8	6-6
4	1 in 120	10.7	14
8	1 in 100	11.2	7.5
4	1 in 100	23	15.6
6	1 in 100	63.5	48.8
6	1 in 800	47.2	19.3
6	1 in 60	75	59.3
6	1 in 100	68	43:8
8	1 in 160	54.	83.4
6	1 in 200	523	29-2
8	1 in 820	49	21.8
6	1 in 400	48.5	19-6
6	1 in 800	47:2	18.8
8	Level	46	00

Du Buât's formula, therefore, gives larger results than the experiments in the two first cases, because the water received at one end only barely filled it, and the pipe was not full at the lower end; but less in the others. If in these the head due to the im-

^{*} Adcock's Engineer's Pocket Book, 1852, pp. 261 and 262.

pulse of entry, at the upper end, and at the side junctions, were known, and the proper hydraulic inclination determined by the experiments, the formulæ would be found to give larger approximate results in every case, as might have been expected from the sewage-water used. In the last eight experiments it is stated*, that "the water was admitted at the head of the pipe, and at five junctions or tributary pipes on each side, so regulated as to keep the main pipe full," and that "without the addition of junctions the transverse sectional area of the stream of water near the discharging end was reduced to one-fifth of the corresponding area of the pipe, and that it required a simple head of water of about 22 inches to give the same result as that accruing under the circumstances of the junctions." It is also stated, that "in the case of the 6-inch pipe, which discharged 75 cubic feet per minute, the lateral streams had a velocity of a few feet per minute."

Now, the head of "about 22 inches" is wholly neglected in the foregoing calculations, though in a pipe 100 feet long it would be equal to an inclination of 1 in 55! It however includes three elements at least, viz. the portion due to the orifice of entry, the portion due to the velocity in the pipe, and the portion due to friction. Let us assume the case of the horizontal pipe, which discharged 46 cubic feet per minute†. This is equal to a mean velocity of

^{*} Adcock's Engineer's Pocket Book, 1852, pp. 261 and 262.

[†] The horizontal pipe would discharge equally at both ends, unless there was a head of water at either, or an equivalent in

46.9 inches per second; with this velocity, we find from Table VIII. the hydraulic inclination of a 6-inch pipe to be 1 in 94, and, therefore, the head due to friction in a pipe 100 feet long is 12.7 inches. Assuming the coefficient for the orifice of entry and velocity to be .815, we also find from Table II. a head of 4½ inches due to these. We then have,

Head due to the veloc	ity and o	rifice	of		
entry		•		4.25	inches
Head due to the resis	stance of	fricti	on	12.70	,,
Radius of pipe.		•		3.00	"
	Total	•		19.95	

which is about 2 inches less than the observed head: this, however, is not stated definitely. It is therefore evident, that the formula gives, if anything, larger results than these experiments*, as might have been expected, instead of less in the ratio of 2 to 3, as is stated in the Report.

Wherever junctions are applied, as in the examples above referred to, the formulæ in general use require correction; for the quantity of water then flowing below each junction is increased. A certain amount of error is, perhaps, inseparable from every calculation of this kind; but before we condemn formulæ deduced from experiment by men every way quali-

the velocity of approach. Of course, a smaller pipe with a fall, must be better than the larger one with none at all, in preventing deposits.

^{*} This is also true of the other formulæ, for finding the discharge from pipes, given in this work.

fied for the task, it would be well that we should learn to understand and properly apply them.

The diameter of a short pipe gives in itself the means of increasing very considerably the surface inclination of the fluid stream, by reducing the section at the lower end. If we assume a horizontal pipe 50 feet long and 6 inches in diameter, we perceive, that if the receiving end be full, and the discharging end one-third full, this inclination will be $\frac{6-2}{50\times 12} = \frac{1}{150}$; and that the discharging end cannot be kept full unless a head of several inches be maintained at the receiving end, or an equivalent from a lateral supply. When the pipe is about two diameters long it becomes a short tube; and when the length vanishes, the transverse section becomes, simply, a discharging orifice.

We have been led into the foregoing remarks, not from any desire to find fault with a Report containing so much valuable information as the one referred to, but for the purpose of defending from unmerited reproach, in a *Blue Book*, the researches in this department, of

> "Those dead but sceptred sovereigns who still rule Our science from their urns—"

Du Buât, Young, Eytelwein, Prony, and others.

We do not pretend to any particular accuracy in the sketches scattered throughout the work; they are only intended to illustrate the text, and were sketched while writing it, without further aim; neither do we pretend to have entered fully into the principles or practice of hydraulics, our object being to select, construct, and arrange useful hydraulic formulæ, experiments, and Tables for the use of all classes of engineers. We make, however, no apology for preferring formulæ, in their simplicity, to any written rules which may be deduced from them, as being in every way more general, concise, and elegant. In conclusion, it is hoped that any errors of consequence in the work, will be found corrected in the errata.

Roden Place, Dundalk, January, 1853.

DISCHARGE OF WATER

FROM

ORIFICES, WEIRS, PIPES, AND RIVERS.

SECTION I.

APPLICATION AND USE OF THE TABLES, FORMULÆ, &C.

To find the velocity of a falling body from the height fallen, or the height fallen from the velocity.

Rule. — Multiply the square root of the height in inches by 27.8, and the product will be the velocity in inches.* To find the height from the velocity, square the velocity in inches and divide the square by 772.84, the quotient will be the height in inches. See equation (1). Table II., column 1, will give the velocity from the height, found in the column of "altitudes," or the height from the velocity, directly.

EXAMPLE 1.—What is the velocity acquired by a heavy body falling $\frac{1}{8}$ th of an inch? In the Table opposite to $\frac{1}{8}$ th of an inch, found in the column headed "altitudes h," we find 9.829 in column 1, for the required velocity, in inches per second.

Example 2.—What is the velocity acquired by a

* The square root of the height in feet multiplied by 8.025 gives the velocity per second in feet; and the square of the velocity in feet divided by 64.4 will give the height in feet.

fall of 11 feet 3 inches? Opposite to 11 feet 3 inches, as before, we find 323.007 inches, for the velocity required.

EXAMPLE 3.—What height must a heavy body fall through to acquire a velocity of 40½ feet per second? Here 40½ feet is equal 486 inches, opposite to the nearest number to which, found in column 1, we find 25 feet 6 inches for the required fall. In this example, the nearest number to 486 found in the Table is 486·301. The difference ·301 corresponds, very nearly, to \$2 ths of an inch in altitude, and, therefore, the true head according to the rule would be 25′ 6¾"; but for all practical purposes the difference is immaterial.

By means of Table II. we can find, directly, or by simple interpolation, the velocity due to all heights from τ_{00} part of an inch up to 40 feet, and the heights from the velocities. For a greater height than 40 feet it may be divided by 4, 9, or some square number s^2 , and the velocity found for the quotient, from the Table, multiplied by 2, 3, or s, the square root of the divisor, will give the velocity required.

EXAMPLE 4.—What is the velocity acquired by a fall of 45 feet? $\frac{45}{4} = 11'3'$, the velocity corresponding to which, found from the Table, is 323.007. Hence, $323.007 \times \sqrt{4} = 323.007 \times 2 = 646''.014 = 53' 10''.014$ is the velocity per second required. The reverse of this example is equally simple.

Columns 3, 4, 5, 6, 7, 8, 9, 10, 11, and 12 in the Table, give the values of $\sqrt{2gh}$ multiplied by the

coefficients therein stated. These columns will be found of great practical use in finding the mean velocities in the vena-contracta, in the orifice, and in short tubes; and consequently also in finding the mechanical force, as well as the discharge. An examination of the coefficients in the small Tables in Section III., and also of those in Tables I. and V., at the end of the work, will show how much they vary; but those most generally useful, and their products by the theoretical velocity due to different heads, up to 40 feet, are given in the columns referred to.

EXAMPLE 5. — What is the discharge from an orifice 4 inches by 8 inches, the centre sunk 20 feet below the surface of a reservoir? From Table II., we find 430.676 inches equal 35.89 feet for the

theoretical velocity of discharge: hence, $\frac{8 \times 4}{144} \times$

 $35.89 = \frac{2}{9} \times 35.89 = 7.976$ cubic feet per second is the theoretical discharge. If the discharge takes place through a thin plate, or if the inner arrises next the water in the reservoir be *perfectly square*, and the water in flowing out does not fill the passage so as to convert the orifice into a short tube, the coefficient will be found from Table I. to be .603. The true discharge then is $7.976 \times .603 = 4.809$ cubic feet per second.

For the determination of the coefficient suited to any particular orifice, and the circumstances of its position, we must refer generally to the following pages. If in the example just given, the arrises next the reservoir were rounded into the form of the contracted vein, see Fig. 4, the coefficient would increase from .603 to .974 or .956, for a passage not exceeding a couple of feet in length. With the former the discharge would be $7.976 \times .974 = 7.769$ cubic feet, and with the latter $7.976 \times .956 = 7.625$ cubic feet. We may find from Table II. the latter results otherwise. With a head of 20 feet and the coefficient .974, the velocity is 419.48 inches = 34.957 feet; hence, the discharge is $\frac{2}{9} \times 34.957 = 7.768$ cubic feet. With a coefficient of .956, the velocity is 411.73 inches = 34.31 feet, and $\frac{2}{9} \times 34.31 = 7.624$ cubic feet. These results are the same, practically, as those previously found.

If the inner arrises be square, and the passage out be from 18 inches to 2 feet long, the orifice will be converted into a short tube, the coefficient for which is .815. With this coefficient, and a head of 20 feet, we find as before, from Table II., the mean velocity of discharge equals 351 inches = 29.25 feet; hence, the discharge now is $\frac{2}{9} \times 29.25 = 6.5$ cubic feet per second.

The velocities in inches per second, given in Tables II. and VIII., or elsewhere in the following pages, may be converted into velocities in feet per minute, by multiplying by 5, equal $\frac{60}{12}$.

EXAMPLE 6.—The discharge from a small orifice having its centre placed 10 feet below the surface of a

reservoir is 18 feet per minute, what will be the discharge from the same orifice at a depth of 17 feet? The discharges will be to each other as $\sqrt{10}$: $\sqrt{17}$, or as $1:\sqrt{17}$; or, from TABLE III., as 1:1:3038, whence we get the discharge sought equal $1:3038 \times 18 = 23:4684$ cubic feet.

EXAMPLE 7.—What is the value of the expression $c_d \left\{ 1 + \frac{c_d^2}{m^2 - c_d^2} \right\}^{\frac{1}{2}}$ in equation (45), when $c_d = .617$, and m = 2? Here we have—

$$\frac{c_d^2}{m^2 - c_d^2} = \frac{\cdot 617^2}{4 - \cdot 617^2} = \frac{\cdot 3807}{3 \cdot 6193} = \cdot 1052 ;$$

whence the first expression becomes equal to .617 $(1.1052)^{i}$ equal, from Table III., $.617 \times 1.0513 =$ ·649, the value sought. TABLE V. contains the values of this expression for various values of c_d and m, which latter, m, stands for the ratio of the channel to an orifice; and we can immediately find from it, opposite 2 in the first column, and under the coefficient .617 in the sixth column, .649 the value sought. When the head due to the pressure, and to the velocity of approach, are both known, we can determine the new coefficient of discharge by the above expression, and thence the discharge itself. The coefficient suited to the velocity of approach may however be found directly in TABLE V. The usual methods for finding the effects of the velocity of approach, given by d'Aubuisson and others, are incorrect in principle, see Section IV.

EXAMPLE 8. — What is the discharge from an orifice 17 inches long and 9 inches deep, having the upper edge placed 4 inches below the surface, and the

lower edge 13 inches? The expression for the discharge is $\frac{2}{3} \times A\sqrt{2g\,d} \times c_d \left\{ \left(1 + \frac{h_t}{d}\right)^{\frac{3}{2}} - \left(\frac{h_t}{d}\right)^{\frac{3}{2}} \right\}$ equation (43), in which we must take d=9 inches; $h_t=9$ inches; $A=17\times 9=153$ square inches; and $\sqrt{2g\,d}$, found from Table II. = 83.4 inches. We have, also, $\frac{h_t}{d} = \frac{4}{9} = .444$, and hence the value of

 $(1.444)^{\frac{3}{2}} - (.444)^{\frac{3}{2}} = (\text{from Table IV.}) 1.44.$

Assuming the coefficient of discharge to be .617, we then have the discharge in cubic inches per second equal to

$$\frac{2}{3} \times 153 \times 83.4 \times .617 \times 1.44 =$$

$$\frac{2}{3} \times 12760.2 \times .88848 = 7558.$$

Consequently, $\frac{7558}{1728} = 4.374$ is the discharge in cubic feet per second. From equation (6), we get the discharge equal to

$$\frac{2}{3} \times .617 \times 27.8 \times 17 \times \{13^{\frac{3}{4}} - 4^{\frac{3}{4}}\}.$$

But $13^{\frac{3}{2}} - 4^{\frac{3}{2}} = 46.872 - 8$, from Table IV., equal to 38.872, whence the discharge is

$$\frac{2}{3}$$
 × ·617 × 27·8 × 17 × 38·872 = 11·4351 × 17 × 38·872 = 194·3967 × 38·872 = 7557 cubic inches = 4·374 cubic feet, the same as before.

It is shown in equation (31), that by using the mean depth for orifices near the surface, the discharge will approximate very closely to the true discharge, and that even for weirs the error will not exceed 6 per cent. The discharge is then expressed by

 $\cdot 617\sqrt{2g\times 8\frac{1}{2}}\times 9\times 17=$ (from Table II.) $50\cdot 01\times 153=7651\cdot 53$ cubic inches = $4\cdot 427$ cubic feet per second. The head to the centre of the orifice is here $8\frac{1}{2}$ inches, and the depth of the orifice 9 inches, therefore, in equation (31), h=d very nearly; and, therefore, this result must be multiplied by $\cdot 989$, as shown in that equation; then $\cdot 989\times 4\cdot 427=4\cdot 378$ cubic feet, which gives a result differing from those otherwise found, by a very small quantity, which, practically, is of no value. By means of Table VI. the discharge from rectangular orifices near the surface can be found with very great facility.

We may always find the discharge from an orifice near the surface with sufficient accuracy, for practical purposes, by taking the head to the centre, in the same manner as if the orifice were sunk to a considerable depth; then by applying the corrections given in equation (31); or if the orifice be circular, those given in equation (28); extreme accuracy, according to the correct formula, is obtainable.

Example 9.—What is the discharge from a circular orifice 4 inches in diameter, having its centre placed 4 inches below the surface, when the coefficient of discharge is $\cdot 617$? The area of the orifice is $4 \times 4 \times \cdot 7854 = 12 \cdot 566$ square inches. The velocity in the orifice at the mean depth of 4 inches, with a coefficient of $\cdot 617$, is $34 \cdot 31$ inches, whence the discharge is $12 \cdot 566 \times 34 \cdot 31 = 431 \cdot 139$ cubic inches $= \cdot 2496$ cubic feet per second, or $14 \cdot 97$ cubic feet per minute. By means of Table IX. the discharge in cubic feet per minute can be found very readily when the velocity, $34 \cdot 31$ inches per second, is known. Thus,

	C	Cubic feet.			
For a vel	ocity of	30.00	the disch	he discharge is	
,,	,,	4.00	,,	,,	1.745
,,	,,	.30	"	,,	0.131
,,	,,	·01	,,	,,	0.004
,,	,	34.31	,,	,,	14.969

By applying the coefficient found from equation (28), which is .992, when the depth at the centre is twice the radius, as it is in this example, we get $.992 \times 14.97 = 14.85$ for the correct discharge in cubic feet per minute. Here the difference in the results is only 1 in 125.

The application of TABLE VI. will enable us to find the discharge from rectangular orifices near the surface very quickly. Resuming "Example 8," the discharge may be found from this Table for each foot in length of the orifice, as follows. The discharge in cubic feet per minute, when the coefficient is .617 for a notch 1 foot long and 13 inches deep, is 223 323; and for a notch of 4 inches deep, 38:116; therefore, the discharge from an orifice 9 inches deep, with the upper edge 4 inches below the surface, is 223.323 -38.116 = 185.207 cubic feet per minute. But as the length of the orifice is 17 inches, this must be multiplied by $\frac{17}{12}$, and the product 262.377 is the discharge in cubic feet per minute; this is equal to a discharge of 4:373 cubic feet per second, and agrees with that before found. This is the simplest way of finding the discharge from rectangular orifices near the surface.

EXAMPLE 10.—What is the discharge in cubic feet

per minute, from an orifice 2 feet 6 inches long and 7 inches deep, the upper edge being 3 inches below the surface, and the coefficient of discharge :628? From TABLE VI. we find the discharge from a notch 1 foot long and 10 inches deep to be 153:353, and for a notch 3 inches deep, 25:199. The difference, or 128:154, multiplied by 2½, will be the discharge required; viz. 2½ × 128:154 = 320:385 cubic feet per minute.

Example 11.—The size of a channel is 2.75 times the size of an orifice, what is the coefficient of discharge when that for a very large channel in proportion to the orifice is .628? We find from TABLE V. the coefficient to be .645, when the approaching water suffers full contraction. By attending to the auxiliary Tables in the text, we find, for this case, $\frac{\text{orifice}}{\text{channel}} = \frac{1}{2.75} = .36.$ We must, therefore, multiply 2.75 by .857, which gives 2.36 for the ratio of the mean velocities in the orifice and in the channel approaching it. With this new value of the ratio of the channel to the orifice, we find, as before, the value of the coefficient from TABLE V. to be .651. The remarks throughout the work, with the auxiliary tables, will be found of much use in determining the coefficients for different ratios of the channel to the orifice. notch, or weir, and the corrections suited to each. If in this example we were considering,—other things being the same,—the alteration in the coefficient for a notch, or weir, it would be found from the Table, column 4, to be .672 instead of .645 found in column 3, for an orifice sunk some depth

below the surface. For the corrections suited to mean and central velocity, and to the nature of the approaches, we must refer to the body of this work and to the auxiliary tables therein at the end of Section IV.

Example 12.—What is the discharge over a weir 50 feet long; the circumstances of the overfall, crest, and approaches, being such that the coefficient of discharge is 617, when the head measured from the water in the weir basin, 6 feet above the crest, is 17½ inches? Table VI. will give the discharge in cubic feet per minute, over each foot in length of weir, for various depths up to 6 feet. It is divided into two parts; the first for "greater coefficients," viz. 667 to 617; and the second for "lesser coefficients," viz. 606 to 518. The coefficient assumed being 617, we find the discharge over 1 foot in length, with a head of 17½ inches, to be 348.799 cubic feet per minute; hence the required discharge is 50 × 348.799 = 17439.95 cubic feet.

The determination of the coefficient suited to the circumstances of the overfall, crest, approaches, and approaching section, will be found discussed elsewhere through this work. The valuable Table derived from Mr. Blackwell's experiments will also be of use; but the heads being taken at a much greater distance back from the crest than is generally usual, the coefficients taken from it for heads greater than 5 or 6 inches, will be found under the true ones for heads measured immediately at or about 6 feet, above the crest. For heads measured on the crest, the small Table of coefficients in Section III., applicable to the purpose, will be of use.

EXAMPLE 13.—What is the mean velocity in a large channel, when the maximum velocity along the central line of the surface is 31 inches per second? TABLE VII. gives 25.89 inches for the required velocity, and for smaller channels 24.86 inches. In order to find the mean velocity at the surface from the maximum central velocity, the latter must be multiplied by .914.

The velocity at the surface is best found by means of a floating hollow ball, which just rises out of the The velocity at a given depth is best found by means of two hollow balls connected with a link, the lower being made heavier than the upper, and both so weighted by the admission of a certain quantity of water that they shall float along the current, the upper one being in advance but nearly vertical over the other. The velocity of both will then be the velocity at half the depth between them. velocity at the surface, found by means of a single ball, being also found, the velocity lost at the half depth is had by subtracting the common velocity due to the linked balls from that of the single ball at the surface. The velocity at any given depth is then easily found by a simple proportion; but the result will be most accurate when the given depth is nearly half the distance between the balls, which distance can never exceed the depth of the channel. Pitot's tube, Woltmann's tachometer, the hydrometric pendulum, the rheometer, and several other hydrometers. have been used for finding the velocity; but these instruments require certain corrections suited to each separate instrument, as well as kind of instrument,

and are not so correct or simple, for measuring the velocity in open channels, as a ball and linked balls.

Example 14.—What is the discharge from a river having a surface inclination of 18 inches per mile, or 1 in 3520, 40 feet wide, with nearly vertical banks, and 3 feet deep? The area is $40 \times 3 = 120$ feet, and the border $40 + 2 \times 3 = 46$ feet; therefore the hydraulic mean depth is $\frac{120}{46} = 2.61$ feet = 2 feet 7.3 inches*. With this and the inclination we find from Table VIII. $28.27 + 2.75 \times \frac{1.3}{6} = 28.87$ inches per second = $28.87 \times 5 = 144.35$ feet per minute for the mean velocity; hence we get $144.35 \times 120 =$ 17,322 cubic feet per minute for the required discharge. For channels with sloping banks we have only to divide the border, which is always known, into the area for the hydraulic mean depth, with which, and the surface inclination, we can always find the velocity by TABLE VIII., and thence the discharge. Unless the banks of rivers be protected by stone pavement or otherwise, the slopes will not continue permanent; it is therefore almost useless to give the discharges for channels of particular widths and side slopes. When the mean velocity is once known, the remaining calculations are those of mere mensuration, and they should be made separately. This example may also be solved, practically, by means of Tables XI, and XII. A channel 40 × 3

^{*} For greater hydraulic depths than 144 inches, the extent of the Table, divide by 9, and find the corresponding velocity. This multiplied by 8 will be the velocity sought.

has the same conveying power as one 70×2 , Table XI., which latter, Table XII. discharges with a fall of 18 inches in the mile, 17,157 feet; or about one per cent. less than that previously found.

Example 15.—The diameter of a very long pipe is $1\frac{1}{2}$ inch, and the rate of inclination, or whole length of the pipe divided by the whole fall, is 1 in $71\frac{1}{2}$; what is the discharge in cubic feet per minute? The hydraulic mean depth, or mean radius, is $\frac{1\cdot 5}{4}=\cdot 375$ inches $=\frac{3}{8}$ inch. Consequently we find from Table VIII. the velocity in inches per second equal to $25\cdot09-1\cdot92\times\frac{1\cdot 5}{10}=25\cdot09-29=24\cdot80$. The discharge in cubic feet per minute for a $1\frac{1}{2}$ -inch pipe is now found most readily by means of Table IX., as follows:—

	C	Cubic feet.			
For a velo	harge is	1.227			
,,	,,	4.0	,,	,,	.245
,,	,,	•8	,,	,,	.049
,,	,,	24.8	,,	,,	1.521

Whence the discharge in cubic feet per minute is 1.521.

For short pipes, of 100 or 200 feet in length, and under, the height due to the velocity and orifice of entry must be deducted from the whole height to find the proper hydraulic inclination, and also the height due to bends, curves, cocks, slides, and erogation. The neglect of these corrections has led some writers into mistakes in applying certain formulæ, and in test-

ing them by experimental results obtained with short pipes. We shall now apply the Tables to the determination of the discharge from short pipes, and compare the results with experiment, referring generally to equation (153) and the remarks preceding it for a correct and direct solution.

EXAMPLE 16.—What is the discharge in cubic feet per minute from a pipe 100 feet long, with a fall or head of 35 inches to the lower end, when the diameter is 11 inch? Find also the discharge from pipes 80 feet, 60 feet, 40 feet, and 20 feet, of the same diameter and having the same head. If the water be admitted by a stop-cock at the upper end, the coefficient due to the orifice of entry will probably be about '75 or less, 815 being that for a clear entry to a short cylindrical tube. The approximate inclination is $\frac{100 \times 12}{35} = 1$ in 34.3; but as a portion of the fall must be absorbed by the velocity and orifice of entry, we may assume for the present that the inclination is 1 in 35. With this inclination and the mean radius $\frac{1\frac{1}{8}}{4} = \frac{3}{8}$ inches, we find the mean velocity from TABLE VIII. to be 38.06 inches. Now when the coefficient due to the orifice of entry and velocity is .75, we find from TABLE II. the head due to this velocity to be $3\frac{3}{8}$ inches nearly, whence $35 - 3\frac{5}{8} = 31\frac{5}{8} = 31 \cdot 625$ inches is the height due to friction, and $\frac{100 \times 12}{31.625}$ equals 1 in 37.9, the inclination, very nearly. With this new inclination we find, as before, from TABLE VIII. the mean velocity of discharge to be now 36.35

inches; and by repeating the operation we shall find the velocity to any degree of accuracy in accordance with the table, and the shorter the pipe is, the oftener must it be repeated. The height due to 36.35 inches taken from Table II. as before, with a coefficient of 750, is $3\frac{1}{5} = 3.125$ inches. The corrected fall due to the friction is now 35 - 3.125 = 31.875.

and $\frac{1200}{31.875}$ equal 1 in 37.6, the corrected inclination. With this inclination we find the corrected velocity to be now 36.53 inches per second. It is not necessary to repeat the operation again. The discharge determined from Table IX. is as follows:—

	C	Cubic feet			
For a velo	ocity of	30.00	the disc	harge is	1.841

,,	"	· 5 0	,,	,,	.031
,,	"	.03	"	,,	.002
*)	,,	36.53	,,	"	2.242

The experimental discharge found by Mr. Provis was 2.264 cubic feet per minute in one experiment, and 2.285 in another. The discharge from the shorter pipes may be found in a similar manner, and we place the results alongside the experimental ones given in the work referred to below* in the following short table:—

^{* &}quot;Transactions of the Institution of Civil Engineers," vol. ii. p. 203. "Experiments on the Flow of Water through small Pipes." By W. A. Provis. The small Tables in Sections VI. and VIII. of this edition give at once the coefficient to be multiplied by $\sqrt{2g_H}$, or $8\sqrt{H}$, to find the velocity when the ratio of the diameter to the length of the pipe is known. They will be found of great advantage in calculating directly the velocity from short pipes. For long pipes, see the Table pp. 42 and 43.

Length of pipe, in feet.	Head, in inches.	Observed discharge, in cubic feet.	Velocity per second.	Head due to the orifice and velocity.	Head due to friction.	Hydraulio inclinations.	Calonisted velocity.	Calculated discharge.

EXPERIMENTAL AND CALCULATED DISCHARGES FROM SHORT PIPES.

The velocities in the fourth column have been calculated by the writer from the observed quantities discharged, from which the height due to the orifice of entry and velocity in column 5 is determined, and thence the quantities in the other columns as above shown. The differences between the experimental and calculated results are not large, and had we used a lesser coefficient than '750 for calculating the reduction of head due to the velocity, stop-cock, and orifice of entry, say '715, the calculated results, and those in all of Mr. Provis's experiments in the work referred to, would be nearly identical.*

EXAMPLE 17.—It is proposed to supply a reservoir near the town of Drogheda with water by a long pipe, having an inclination of 1 in 480, the daily supply to be 80,000 cubic feet; what must the diameter of

^{*} In a late work, "Researches in Hydraulics," the author is led into a series of mistakes as to the accuracy of Du Buat's and several other formulæ, from neglecting to take into consideration the head due to the velocity and orifice of entry when testing them by the experiments above referred to.

the pipe be? The discharge per minute must be $\frac{80,000}{1440} = 56$ * cubic feet, nearly. Assume a pipe whose "mean radius" is 1 inch, or diameter 4 inches, and the velocity per second found from Table VIII. will be 14.41 inches. We then have from Table IX.,

122.,		Inches.		Cubic feet		
For a velocity of		10.00	a disch	4.363		
,,	,,	4.00	,,	,,	1.745	
,,	,,	•40	,,	,,	.175	
,,	,,	.01	,,	,,	·00 4	
,,	,,	14.41	,,	,,	6.287	

The discharge from a pipe 4 inches in diameter would be therefore 6.287 cubic feet per minute. We then have

 $4^{\frac{5}{2}}:d^{\frac{5}{2}}::6.287:56$, or $1:d^{\frac{5}{2}}::196:56::1:286$; therefore $d^{\frac{5}{2}}=286$, and d=9.61 inches, nearly, as may be found from Table XIII., &c. This is nearly the required diameter. It is to be observed that the diameters thus found will not always agree exactly with those found from Du Buât's or other formulæ, nor with each other, because the discharges are not strictly as $d^{\frac{5}{2}}$; but in practice the difference is immaterial, and the approximative value thus found can be easily corrected. If we assumed a pipe whose diameter is 1, the operation would have been more simple; for the velocity would then be, Table VIII., at the given inclination, 6.4 inches; and the discharge 175 cubic feet, Table IX. Hence we get $d^{\frac{5}{2}}$

^{*} Hydraulic Tables, Weale, 1854, give at once this discharge for a pipe between 9 and 10 inches diameter, also the Table, p. 42.

 $\frac{56}{\cdot 175} = 320$, and, therefore, Table XIII., d = 10 inches nearly, which differs about half-an-inch from the former value, 9.6 inches, found by assuming a pipe of 4 inches to calculate from. It is necessary to understand that different results must be expected, in working from practical formulæ, for different operations. When once an approximative value is obtained, it can be easily corrected to any required degree of accuracy.

Again the velocity in inches per second, from a cylindrical pipe 6 inches in diameter, is nearly equal to the discharge in cubic feet per minute; and as $6^{\frac{5}{2}} = 88\cdot 2$, we have $88\cdot 2$: the velocity in inches per second from a 6-inch pipe: the discharge per minute from a pipe whose diameter is d. Hence this proportion would enable us to find, very nearly, the discharge from the diameter and fall; or the diameter from the discharge and fall by finding the velocity only, due to a 6-inch pipe. See Table pp. 42 and 43.

Example 18.—The area of a channel is 50 square feet, and the border 20.6 feet; the surface has an inclination of 4 inches in a mile; what is the mean velocity of discharge? $\frac{50}{20.6} = 2.427 \text{ feet} = 29.124$ inches is the hydraulic mean depth; and we get from Table VIII. $12.03 - \frac{1.30 \times .876}{6} = 12.03 - .19 = 11.84$ inches per second for the required velocity. Though this velocity will be found under the true value for straight clear channels, it will yet be more correct for ordinary river courses, with bends

and turns, of the dimensions given, than the velocity found from equation (114). For a straight clear channel of these dimensions, Watt found the mean velocity to be 13.5 to 14 inches; that is to say, 17 at top, 10 at bottom, and 14 in the middle. Our formula $v = 140 \ (r \ s)^{\frac{1}{2}} - 11 \ (r \ s)^{\frac{1}{3}}$ gives v = 1.143 feet, or nearly a mean of these two.

EXAMPLE 19.—A pipe 5 inches in diameter, 14,637 feet in length, has a fall of 44 feet; what is the discharge in cubic feet per minute? The inclination is $\frac{14,637}{44} = 332.7$, and mean radius $\frac{5}{4} = 1\frac{1}{4}$. We then find from Table VIII. the velocity equal to $19.81 + \frac{41 \times 4.8}{12.5} = 19.81 + 16 = 19.97$, or 20 inches per second very nearly; and by Table IX. the discharge in cubic feet per minute is, as before found to be, 13.635. The Table, p. 42, gives, by inspection, 13.6 feet.

EXAMPLE 20.—What is the velocity of discharge from a pipe or culvert 4 feet in diameter, having a fall of 1 foot to a mile? Here $s = \frac{1}{5280}$, and r = 1 foot. We then find the velocity of discharge from TABLE VIII. to be 14.09 inches, equal to 1.174 feet per second. By calculating from the different formulæ referred to below, we shall find the velocities, when rs = .0001894, and $\sqrt{rs} = .01376$, as follows.

We have calculated this example from the several formulæ above referred to, whether for pipes or rivers. in order that the results may be more readily compared. The formula from which the velocities and tables for the discharges of rivers are usually calculated is, for measures in feet, $v = 94.17 \sqrt{r}$ s. This gives the mean velocity, for the foregoing example, equal to 1.295 feet per second. This is the same as is found from my general formula for all velocities; but the particular expression, v = 99.17 \sqrt{rs} , is only suited for velocities of about 15 inches per second; the results found from it for lesser velocities are too much, and for higher velocities too little, if bends and curves be allowed for separately-For ordinary practical purposes the result of Du Buât's general formula, equation (81), may be safely adopted; and we have, accordingly, preferred retaining the results in TABLE VIII. calculated for our first edition from it, notwithstanding the greater accuracy and simplicity of our own general equation (119 A)

[•] These two formulæ of D'Aubuisson's are, simply, adoptions of Eytel wein's and Prony's.

for the velocity in pipes and rivers, viz., $v = 140 (rs)^{\frac{1}{2}}$.

Dr. Young's formula gives lesser results for rivers and large pipes than Du Buât's, but they are too small unless when the curves and bends are numerous and sudden. Girard's formula (86) is only suited for small velocities in canals containing aquatic plants, and it is entirely inapplicable to rivers or regular channels for conveyance of water. A knowledge of various formulæ, and their comparative results, applied to any particular case, will be found of great value to the hydraulic engineer, and the differences in the results show only an amount of error that may be expected in all practical operations, and which becomes of less importance when we consider that by increasing the dimensions of a channel every way, by only one-third, we shall more than double its discharging power. See Table XIII.

Example 21.—Water flowing down a river rises to a height of 10½ inches on a weir 62 feet long; to what height will the same quantity of water rise, on a weir similarly circumstanced, 120 feet long? $\frac{62}{120}$ =:517, nearly. In Table X. we find, by inspection, opposite to :517, the ratio of the lengths, the coefficient :644, rejecting the fourth place of decimals; whence 10½ ×:644=6.76 inches, the height required. When the height is given in inches it is not necessary to take out the coefficient to further than two places of decimals.

EXAMPLE 22.—The head on a weir 220 feet long is 6 inches; what will the head be on a weir 60 feet long, similarly circumstanced, the same quantity of water

flowing over each? $\frac{60}{220}$ =·273. As this lies between ·27 and ·28, we find from TABLE X. the coefficient ·4208; hence $\frac{6}{\cdot 4208}$ =14·26 inches, the head required.

TABLE X. will be found equally applicable in finding the head above the pass into weir basins, and above contracted water channels. See Section X.

EXAMPLE 23.—A river channel 40 feet wide and 4.5 feet deep is to be altered and widened to 70 feet; what must the depth of the new channel be so that the surface inclination and discharge shall remain unaltered? In "Table XI., of equally discharging rectangular Channels," we find opposite to 4.54, in the column of 40 feet widths, 3 in the column of 70 feet widths, which is the depth required in feet.

EXAMPLE 24.—It is necessary to unwater a river channel 70 feet wide and 1 foot deep, by a rectangular side cut 10 feet wide; what must the depth of the side cut be, the surface inclination remaining the same as in the old channel? In Table XI. we find 4.5 feet for the required depth. When the width of a channel remains constant, the discharge varies as $\sqrt{rs} \times d$, in which d is the depth; and when the width is very large compared with the depth, the hydraulic mean depth r approximates very closely to the depth d, and therefore d = r; consequently the discharge then varies as $d^{\frac{3}{2}} \times s^{\frac{1}{2}}$, and when the discharge is given $d^{\frac{3}{2}}$ must vary inversely as $s^{\frac{1}{2}}$; or more generally $dr^{\frac{1}{2}}$ must vary inversely, as $s^{\frac{1}{2}}$, when the width and discharge remain constant.

In narrow cuts for unwatering, it is prudent to make the depth of the water half the width of the

cut very nearly, when local circumstances will admit of these proportions; for then a maximum effect will be obtained with the least possible quantity of excavation; but for rivers and permanent channels the proper relation of the depth to the width must be regulated by the principles referred to in Section IX.

TABLE XI. is equally applicable, whether the measures be taken in feet, yards, or any other standards whatever.

EXAMPLE 25.—A new river channel is to have a fall of eighteen inches in a mile, and must discharge 18,700 cubic feet per minute, what shall the dimensions be? In Table XII., in the column of 18 inches per mile, we shall find opposite to 18,766, that a primary channel $70 \times 2 \cdot 125$ will be sufficient; and opposite to $2 \cdot 125$ in Table XI. we shall find the equivalent rectangular channels $60 \times 2 \cdot 37$; $50 \times 2 \cdot 70$; $40 \times 3 \cdot 19$; $35 \times 3 \cdot 52$; $30 \times 3 \cdot 96$; $25 \times 4 \cdot 61$; $20 \times 5 \cdot 58$; $15 \times 7 \cdot 29$; and $10 \times 11 \cdot 37$, to select from. If the sides shall have any given slopes, the discharge will not be practically affected as long as the depth and area of the rectangular channel and the one with sloping banks remain the same. See Section IX.

EXAMPLE 26.—A pipe 100 feet long and 1 inch in diameter has a head of 150 feet over the lower end, what will be the discharging velocity? Here r = .020833 in feet, and s = 1.5, therefore r = .03125. Hence by formulæ $(119A) v = 140 \times (.03125)^{1} - 11 \times (.03125)^{1} = 140 \times .1766 - 11 \times .315 = 24.724 - 3.465 = 21.259$ feet per second. If allowance is required for the orifice of entry, the velocity is corrected as follows. A square orifice of entry has a coefficient of .815. The head due to this coefficient for a

velocity of about $20\frac{1}{3}$ feet, or 246 inches, is about 10 feet, Table II.—The head due to friction is therefore 150-10=140 feet, and $s=\frac{100}{140}=1\cdot4$; rs now becomes $1\cdot4\times \cdot020833=\cdot02917$. Hence $v=140\sqrt{rs}-11\sqrt[3]{rs}$ now becomes $140\times \cdot171$ $-11\times \cdot308$ nearly, equal to $23\cdot940-3\cdot388=20\cdot552$ feet, the velocity for a square junction.

Example 27.—A sewer 9 feet in diameter has a fall of 2 feet per mile, what will be the velocity and discharge of water flowing through it when full? Here r = 2.25 and $s = \frac{1}{2640}$, therefore rs = .0008523, $(rs)^{i} = .02919$ and $(rs)^{i} = .0948$; and by formula (119A) we have $v = 140 (r s)^{t} - 11 (r s)^{t} = 140 \times$ $0.02919 - 11 \times 0.0948 = 4.0866 - 1.0428 = 3.0438$ feet per second. Hence the discharge per minute is $9^2 \times .7854 \times 3.0438 \times 60 = 63.62 \times 182.6 = 11,617$ cubic feet nearly. The velocity from a circular pipe or sewer is however greatest when the circumference is open for about 781 degrees at the top, but the velocity of sewage matter would not be equal to that of water. It would vary according to the dilution in the sewer, and 50 per cent. should be allowed, at least, in deduction, unless the dilution be very considerable.

The Table for the values of r s and v, calculated from the formula (119 A) Sec. VIII., will give the velocity at once when r s is known, and r s when the velocity is known, from the latter of which a definite value of r or s can be fixed upon, when the other may be found, by an operation of simple division.

Example 28.—Water is to be pumped through a

pipe 3000 feet long and 2 feet in diameter, with a velocity not exceeding 4 feet per second, what head must be allowed extra for friction in the pipe in calculating horse power? We shall find from our TABLE of the values of the velocity and product of the hydraulic mean depth and hydraulic inclination, given near the conclusion of Section VIII., that for a velocity of 4 feet per second r = 00142. The diameter of the pipe is 2 feet, therefore r = .5, whence $s = \frac{.00142}{.5} = .00284$, and as the length of the pipe is 3000 feet we get $3000 \times .00284 = 8.52$ feet, the head required. The TABLE, p. 43, would give 9.6 feet nearly, which corresponds with Du Buât's formula. If the velocity in the pipe was 10 feet instead of 4 feet per second, then, from our table, rs = .007576, and $\frac{rs}{r} = s = \frac{.007576}{.5} = .015152$, and, therefore, $h = ls = 3000 \times .015152 = 45.456$ feet, or about six times as much as when the velocity was only 4 feet per second. The great loss of head arising from pumping at high velocities, from friction alone, is therefore apparent. Were the velocity double, or 8 feet per second, the head would be 30 feet nearly, or from the TABLE, p. 43, 31.6 feet.

For velocities of about 2.1 feet per second, v is equal to $100 \sqrt{rs}$, and for velocities of about $5\frac{1}{2}$ feet per second, $v = 110 \sqrt{rs}$. If l be the length of a pipe, we would find in the former case the head h in feet due to friction from the formula $h = \frac{lv^2}{10,000 \, r} = ls$; and in the latter $h = \frac{lv^2}{12,100 \, r} = ls$.

In questions of this kind, however, the diameter of

a pipe, d should be used in preference to the hydraulic mean depth, and as d = 4r we shall find in the first case $h = \frac{lv^2}{2500 d} = ls$; and in the second case, $h = \frac{lv^2}{3025 d} = ls$.

If we wish to substitute the fall per mile for the hydraulic inclination, the first of these will again become $h = \frac{2 \cdot 11 \, v^2}{d} = ls$ for the loss per mile; and in the second case, $h = \frac{1 \cdot 72 \, v^2}{d} = ls$ for the loss per mile in feet.

If the velocity were so low as about 1 foot per second, then $v = 90 \sqrt{rs}$, and we should find $h = \frac{lv^2}{2025 d} = ls$.

If for the inclination we substitute the fall per mile, this will become $h = \frac{2.61 \, v^{s}}{d} = ls$ for the loss per mile in feet.

The loss of head varies in the same pipe with the velocity, and must be calculated differently, for small and for high velocities, when using the common formulæ. The TABLE near the end of Section VIII. will always give the correct value of rs, and thence $s = \frac{rs}{r}$.

In addition to the loss of head arising from friction, losses also occur from straight or curved bends, from diaphragms, from junctions, and from the orifices of entry and discharge; these must be determined separately for each case, as is shown hereafter, and added together and to the loss arising from friction, and the sum to the height the water is to be raised, before the full or total head for determining the power of an engine can be accurately known.

The TABLE on the next two pages will be found of great practical utility in solving all questions connected with water-pipes and sewers discharging fullydiluted sewage. In using it we can interpolate, by inspection, for intermediate diameters or inclinations. For greater diameters, divide those given by 4, and multiply the corresponding velocity found in the table by 2, and the corresponding discharge in the table by 32. If the object be to find the size of the channel, divide greater given velocities by 2. and multiply the diameters or inclinations found from the table by 4; also divide greater discharges by 32, and multiply the diameters found from the table by 4. The small auxiliary table, p. 43, embodied in the larger one, is of great use in making allowance for the velocity and orifice of entry in short pipes, before finding the head due to friction. The table also gives the different diameters and inclinations which, taken together, give the same velocity or discharge; and it enables us, from inspection, to select that relation of diameter to declivity which is best suited for other engineering aspects of the question. Taken in connexion with TABLES VIII., XI., XII., and XIII., this table completes the means of finding, by inspection, the dimensions, inclinations, velocities, and discharges of every class of water-channel or sewage-conduit required in engineering practice.

TABLE XIV. gives the comparative values of English and French measures; and TABLE XV. gives the weight, specific gravity, and ultimate strength and elasticity of various materials with which the engineer has to operate.

The Velocity in Inches per Second is given in the first horizontal line for each inclination or fall; and the Discharge in Cubic Feet per Minutes in the next following one.

SECTION II.

FORMULÆ FOR THE VELOCITY, AND DISCHARGE, FROM ORIFICES, WEIRS, AND NOTCHES.—COEFFICIENTS OF VELOCITY, CONTRACTION, AND DISCHARGE.—PRACTICAL REMARKS ON THE USE OF THE FORMULÆ.

The quantity of water discharged in a given time through an aperture of a given area in the side or bottom of a vessel, is modified by different circumstances, and varies more or less with the form, position, and depth of the orifice; but the discharge may be easily found, when we have determined the velocity and the contraction of the fluid vein.

VELOCITY.

If g be the velocity acquired by a heavy body falling from a state of rest for one second, in vacuo, then it has been shown by writers on mechanics, that the velocity v per second acquired by falling from a height h, will be

$$(1.) v = \sqrt{2gh}.$$

The numerical value of g varies with the latitude; we shall assume 2 g = 772.84 inches = 64.403 feet. These will give for measures in inches,

$$v = 27.8 \sqrt{h,*}$$
 and $h = \frac{v^*}{772.84} = .001293v^*,$

and for measures in feet,

* The velocities for different heights are given in the column number 1, Table II.

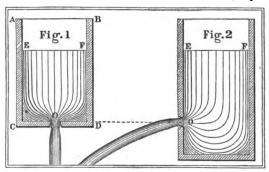

$$v = 8.025 \sqrt{h}$$
, and $h = \frac{v^2}{64.403} = .01553 v^2$.

If v be in feet, and h in inches, then

$$v = 2.317 \sqrt{h}$$
, and $h = \frac{v^2}{5.367} = .1864 v^*$.*

COEFFICIENT OF VELOCITY.

Let the vessel ABCD, Fig. 1, be filled with water to the level EF: then it has been found, by experi-

ment, that the velocity of discharge through a small orifice o, in a thin plate, at the distance of half the diameter outside it, in the vena-contracta, will be very nearly that due to a heavy body falling freely from the height h, of the surface of the water E F, above the centre of the orifice. The velocity of discharge

* The force of gravity increases with the latitude, and decreases with the altitude above the level of the sea, but not to any considerable extent. If λ be the latitude, and h the altitude, in feet, above the mean sea level, then we may, generally, take

$$g = 32.17 (1 - .0029 \cos 2\lambda) \times (1 - \frac{2h}{B})$$

in which R, the radius of the earth at the given latitude is equal to

 $20887600 (1 + .0016 \cos 2\lambda)$.

determined by the equation $v = \sqrt{2gh}$, for falling bodies, is, therefore, called the "theoretical velocity." If we now put v_d for the actual mean velocity of discharge in the vena-contracta, and c_v for its ratio to the theoretical velocity v, we shall get $v_d = c_v v$; and by substituting for v, its value $\sqrt{2gh}$,

$$(2.) v_{\mathsf{d}} = c_{\mathsf{r}} \sqrt{2 g h},$$

c, is termed "the coefficient of velocity;" its numerical value, at about half the diameter from the orifice, is about '974; and, consequently,

$$v_{\rm d} = .974 \sqrt{2 g h}$$
.

This for measures in inches becomes

$$v_{\rm d} = 27.077 \sqrt{h},*$$

and for measures in feet

$$v_{\rm d} = 7.816 \sqrt{h}$$
.

The orifice o, is termed an horizontal orifice in Fig. 1, and in Fig 2 a vertical or lateral orifice. When

* The velocities for different heights calculated from this formula, are given in the column numbered 2, Table II. It has been latterly asserted in a Blue Book that theoretically $v_d =$ $\frac{3}{4}\sqrt{2gh}$. It is not necessary here to combat this error, which confounds the discharge with its velocity, and a single practical fact, applicable only to a thin plate, with a theoretical principle. The experimental discharge approximates to $\frac{1}{2}\sqrt{2gh}$ multiplied by the area of the orifice; but the theoretical velocity $\sqrt{2gh}$ always approximates to the experimental velocity, or $.974 \sqrt{2gh}$, obtained immediately outside the orifice in the vena-contracta. It would be unnecessary to allude to this theory here if it were not supported and put forward by three eminent engineers whose authority may mislead others. Vide p. 4. Brief observations of Messrs. Bidder, Hawksley, and Bazalgette on the answers of the Government Referees on the METROPOLITAN MAIN DRAINAGE, Ordered by the House of Commons to be printed 13th July, 1858.

small, each is found to have practically the same velocity of discharge, when the centres of the contracted sections are at the same depth, h, below the surface; but when lateral orifices are large, or rather deep, the velocity at the centre is not, even practically, the mean velocity; and in thick plates and modified forms of adjutage, the mean velocities are found to vary.

VENA-CONTRACTA AND CONTRACTION.

It has been found that the diameter of a column issuing from a circular orifice in a thin plate, is contracted to very nearly eight-tenths of the whole diameter at the distance of the radius from it, and that at this distance the contraction is greatest. The ratio of the diameter of the orifice to that of the contracted vein, vena-contracta, is not always found constant by the same or different experimentalists.

Eytelwein	,,	1:	∙8	,,	,,	1: .64
Bayer	"	1:	·7854	,,	,,	1: .617

Bayer's value for the contraction has been determined on the hypothesis, that the velocities of the particles of water as they approach the orifice from all sides, are inversely as the squares of their

distances from its centre; and the calculations made of the discharge from circular, square, and rectangular orifices, on this hypothesis, coincide pretty closely with experiments.

FORM OF THE CONTRACTED VEIN.

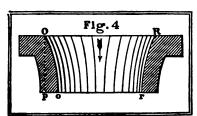

Let o R = d, Fig. 3, be the diameter of an orifice; then at the distance $R = \frac{d}{2}$ the contraction is found to be greatest; we shall assume the contracted diameter $o r = .7854 \ d$. If we suppose the fluid column between o R and o r to be so reduced, that the curve lines R r and o o shall become arcs of circles,

then it is easy to show from the properties of the circle, that the radius cr must be equal to 1.22 d. The mean velocity in the orifice, or, is to that in the

vena-contracta, or, as $\cdot 617:1$; and the mouth piece, $\mathbf{R} r o o$, Fig. 4, in which $o p = \frac{1}{2} o \mathbf{R}$, and $o r = \cdot 7854 \times o \mathbf{R}$, will give for the velocity of discharge at o r, the vena-contracta,

$$v_{\rm d} = .974 \sqrt{2 g h} = 7.816 \sqrt{h},$$

in feet very nearly. In speaking of the velocity of discharge from orifices in thin plates, we always assume it to be the velocity in

the vena-contracta, and not that in the orifice itself,

which varies with the coefficient of discharge, unless in Table II., where the mean velocity in the latter, as representing $c_a \sqrt{2gh}$, is also given.

COEFFICIENTS OF CONTRACTION AND DISCHARGE.

If we put A for the area of the orifice o B, Fig. 3, and $c_o \times A$ for that of the contracted section at o r, then c_o is called the "coefficient of contraction." The velocity of discharge v_d is equal to $c_r \sqrt{2gh}$, equation (2). If we multiply this by the area of the contracted section $c_o \times A$, we shall get for the discharge

$$D = c_{\mathsf{v}} \times c_{\mathsf{e}} \times \mathbf{A} \sqrt{2 g \, h}.*$$

It is evident A $\sqrt{2 g h}$ would be the discharge if there were no contraction and no change of velocity due to the height h; $c_v \times c_o$ is therefore equal to the coefficient of discharge. If we call the latter c_d , we shall have the equation

$$(3.) c_{\rm d} \equiv c_{\rm v} \times c_{\rm e},$$

and hence we perceive that the "coefficient of discharge" is equal to the product of the coefficients of velocity and contraction. In the foregoing expression for the discharge D, h must be so taken, that the velocity at that depth shall be the mean velocity in the orifice A. In full prismatic tubes the coefficients of velocity and discharge are equal to each other.

^{*} The expression c_v c_o $\sqrt{2gh} = c_d \sqrt{2gh}$ is the coefficient of the area A, and, consequently, represents the mean velocity in the orifice; the coefficient of which is, therefore, equal to c_d . The values of the velocity $c_d \sqrt{2gh}$, for different heights and coefficients, are given in Table II.

MEAN AND CENTRAL VELOCITY.

In order to find the mean velocity of discharge from an orifice, it is, in the first instance, necessary to determine the velocity due to each point in its surface, and the discharge itself; after which, the mean velocity is found by simply dividing the area of the orifice into the discharge. The velocity due to the height of water at the centre of a circular, square, or rectangular orifice, is not strictly the mean velocity, nor is the latter in these, or other figures, that at the centre of gravity. When, however, an orifice is small in proportion to its depth in the water, the velocity of efflux determined for the centre approaches very closely to the mean velocity; and, indeed, at depths exceeding four times the depth of the orifice, the error in assuming the mean velocity to be that at the centre of the orifice is so small as to be of little or no practical consequence, and for lesser depths it never exceeds 6 per cent. It is, therefore, for greater simplicity, the practice to determine the velocity from the depth h of the centre of the orifice, unless in weirs or notches; and the coefficients of discharge and velocity in the following pages have been calculated from experiments on this assumption, unless it shall be otherwise stated.

DISCHARGES THROUGH ORIFICES OF DIFFERENT FORMS IN THIN PLATES.

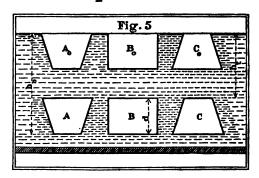

The orifices which we have to deal with in practice are square, rectangular, or circular; and sometimes, perhaps, triangular or quadrangular in form. It will be necessary to give here only the theoretical expressions for the discharge and velocity for each kind of form, but as the demonstrations are unsuited to our present purposes we shall omit them.

TRAPEZOIDAL ORIFICES WITH TWO HORIZONTAL SIDES.

Put d for the vertical depth of an orifice, h_t for the altitude of pressure at top, above the upper side, and h_b for the altitude at bottom, above the lower side, we then get

$$h_{\rm b}-h_{\rm t}=d.$$

Let us also represent the top or upper side of the orifice A or c, Fig. 5, by l_t , and the lower or bottom side by l_b , and put $\frac{l_t + l_b}{2} = l$.

Now, when $l_i = l_b$, the trapezoid becomes a parallelogram whose length is l and depth d; and putting h for the depth to the centre of gravity, we get the equation

$$h_{t} + \frac{d}{2} = h_{b} - \frac{d}{2} = h.$$

The general expression for the discharge, D, through a trapezoidal orifice, A, is then

ne R

(4.) $\mathbf{p} = c_d \sqrt{2g} \times \frac{2}{8} \left\{ l_b h_b^{\frac{3}{2}} - l_t h_{\frac{3}{4}}^{\frac{3}{4}} + \frac{2}{5} (l_t - l_b) \frac{h_b^{\frac{5}{4}} - h_b^{\frac{5}{4}}}{d} \right\}$, in which c_d is the coefficient of discharge; and when the smaller side is uppermost as at c,

(5.)
$$D = c_d \sqrt{2g} \times \frac{2}{3} \left\{ l_b h_b^{\frac{3}{2}} - l_i h_i^{\frac{3}{2}} - \frac{2}{5} (l_b - l_i) \frac{h_b^{\frac{5}{2}} - h_i^{\frac{5}{2}}}{d} \right\}$$

PARALLELOGRAMIC AND RECTANGULAR ORIFICES.

When $l_i = l_b = l$, the orifice becomes a parallelogram, or a rectangle, B, and we have for the discharge

(6.)
$$\mathbf{D} = c_{\mathbf{d}} \sqrt{2g} \times \frac{2}{3} l\{h_{b}^{\frac{1}{3}} - h_{\frac{1}{3}}^{\frac{1}{3}}\}.$$

NOTCHES.

When the upper sides of the orifices A, B, and C, rise to the surface as at A_0 , B_0 , and C_0 , h_t becomes nothing, and we get, as $h_b = d$, for the trapezoidal notch A_0 with the larger side up,

(7.)
$$D = c_d \sqrt{2g} \times \frac{2}{8} d^{\frac{3}{2}} \left\{ l_b + \frac{2}{5} (l_t - l_b) \right\}$$

= $\frac{2}{15} c_d \sqrt{2g} d^{\frac{3}{2}} (2 l_t + 3 l_b);$

for the trapezoidal notch, co, with the smaller side up,

(8.)
$$D = c_d \sqrt{2g} \times \frac{2}{3} d^{\frac{3}{2}} \left\{ l_b - \frac{2}{5} (l_b - l_l) \right\}$$

= $\frac{2}{15} c_d \sqrt{2g} d^{\frac{3}{2}} (2 l_l + 3 l_b),$

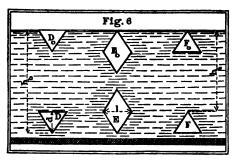

the same in form, but not in value, as the preceding equation; and for a parallelogramic or rectangular notch B_0 ,

(9.)
$$D = c_a \sqrt{2g} \times \frac{2}{3} l d^{\frac{3}{3}} = \frac{2}{3} c_a l d^{\frac{3}{2}} \sqrt{2g}$$

It is easy to perceive that the forms of equations (4) and (5), and also of equations (7) and (8), are identical. The values for the discharge in equations (6) and (9) are equally applicable, whether the form of the orifice be a parallelogram or a rectangle, the only difference being in the value of the coefficient of discharge, c_d , which becomes slightly modified for each form of orifice.

TRIANGULAR ORIFICES WITH HORIZONTAL BASES, AND RECTILINEAL ORIFICES IN GENERAL.

When the length of the lower side, L = 0, the orifice becomes a triangle, D, Fig. 6, with the base upwards.

In this case, equation (4) becomes

(10.)
$$D = c_a \sqrt{2g} \times \frac{2}{3} l_a \left\{ \frac{2}{5} \times \frac{h_b^{\frac{5}{6}} - h_{\frac{3}{4}}^{\frac{3}{2}}}{d} - h_{\frac{3}{4}}^{\frac{3}{2}} \right\};$$

which gives the discharge through the triangular orifice, D.

When $l_i = 0$, in equation (5), the orifice becomes a triangle, r, with the base downwards; in this case, we find for the value of the discharge,

(11.)
$$D = c_d \sqrt{2g} \times \frac{2}{3} l_b \left\{ h^{\frac{3}{5}} - \frac{2}{5} \times \frac{h^{\frac{5}{5}} - h^{\frac{5}{5}}}{d} \right\}.$$

As any triangular orifice whatever can be divided into two others by a line of division through one of the angles parallel to the horizon; and as the discharge from the triangular orifice D or F is the same as for any other on the same base and between the same parallels, we can easily find, by such a division, the discharge from any triangle not having one side parallel to the horizon, and thence the discharge from any rectilineal figure whatever by dividing it into triangles.

If the triangle r be raised so that the base shall be on the same level with the upper side of the triangular orifice p; if, also, the bases be equal, and also the depths, we shall find, by adding equations (10) and (11), and making the necessary changes indicated by the diagram,

(12.)
$$D = c_4 \sqrt{2g} \times \frac{4 l}{15 d} \{h_b^{\frac{5}{2}} + h_t^{\frac{5}{2}} - 2 \times \overline{h_t + d}|^{\frac{5}{2}}\}$$

for the discharge from a parallelogram E with one diagonal horizontal. Now this is the same as the discharge from any quadrilateral figure whatever, having the same horizontal diagonal, and also having the upper and lower angles on the same parallels, or at the same depths, as those of the parallelogram. If the orifices D, F, and E rise to the surface of the water, as at D_0 , E_0 , F_0 , we shall then have for the discharge from the notch D_0 ,

(13.)
$$D = c_4 \sqrt{2g} \times \frac{4}{15} l_4 d^{\frac{3}{2}}$$
:

which for a right angled triangle becomes

$$D = c_d \sqrt{2g} \times \frac{8}{15} d^{\frac{5}{2}}.*$$

For the discharge from the notch Fo,

(14.)
$$D = c_4 \sqrt{2g} \times \frac{6}{15} l_b d^{\frac{3}{2}}:$$

and for the discharge through the notch E,

(15.)
$$D = c_d \sqrt{2g} \times \frac{4l}{15d} \{h_b^{\frac{5}{2}} - 2d^{\frac{5}{2}}\} = c_d \sqrt{2g} \times 9752ld^{\frac{3}{2}}.$$

When the parallelogram E_0 becomes a square l=2 d, and hence,

(16.)
$$D = c_d \sqrt{2g} \times .9752 l^{\frac{6}{2}} \times \sqrt{\frac{1}{8}} = c_d \sqrt{2g} l \times .34478 l^2$$
.

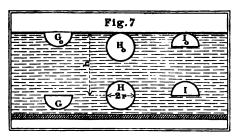

The foregoing equations will enable us to find an expression for the discharge from any rectilineal orifice whatever, as it can be divided into triangles, the discharge from each of which can be determined as already shown in the remark following equation (11.) The examples which we have given will be found to comprehend every form of rectilineal orifice which occurs in practice; but for the greater number of orifices, sunk to any depth below the surface, the

* In the Civil Engineer and Architect's Journal, 1858, p. 370, it is stated that Professor Thompson, Belfast College, gave at the British Association in Leeds for a right angled triangle, for discharges of from 2 to 10 cubic feet per minute, the expression $q = .317 \text{ H}^{\frac{5}{9}}$, in which q is the quantity in cubic feet per minute, and H the head in inches. Now the above equation for a coefficient of .617 becomes, for inch measures, $p = 17.153 \times \frac{8}{15} d^{\frac{5}{2}} = 9.15 d^{\frac{5}{2}}$; or by multiplying by 60, and dividing by 1728, to reduce the discharge to feet per minute, we get $p = .317 d^{\frac{5}{2}}$, identically the same as Professor Thompson derived from his experiments. All sections of a triangular notch are similar triangles, and hence the advantage of a triangular-notch-gauge, where it can be used, as, probably, the coefficient remains constant. Professor Thompson, I believe, first drew attention to this.

discharge will be found with sufficient accuracy by multiplying the area by the velocity due to the centre.

CIRCULAR AND SEMICIRCULAR ORIFICES.

The discharge through circular and semicircular orifices in thin plates can only be represented by means of infinite series. Let us represent by s_1 the sum of the series

$$\begin{split} \left\{ \frac{1}{2} - \left(\frac{1}{2} \cdot \frac{1}{4}\right) \left(\frac{1}{2} \cdot \frac{1}{4}\right) \frac{r^2}{h^2} - \left(\frac{1}{2} \cdot \frac{1}{4} \cdot \frac{8}{6} \cdot \frac{5}{8}\right) \left(\frac{1}{2} \cdot \frac{1}{4} \cdot \frac{8}{6}\right) \frac{r^6}{h^4} \\ - \left(\frac{1}{2} \cdot \frac{1}{4} \cdot \frac{8}{6} \cdot \frac{5}{8} \cdot \frac{7}{10} \cdot \frac{9}{12}\right) \left(\frac{1}{2} \cdot \frac{1}{4} \cdot \frac{8}{6} \cdot \frac{5}{8}\right) \frac{r^6}{h^6} - \&c. \right\} : \end{split}$$

Let us also represent by s₂ the sum of the series

$$\frac{2}{8^{\circ}1416} \left\{ \left(\frac{1}{2} \cdot \frac{1}{8} \right) \frac{r}{h} + \left(\frac{1}{2} \cdot \frac{1}{4} \cdot \frac{8}{6} \right) \left(\frac{1}{8} \cdot \frac{2}{5} \right) \frac{r^{3}}{h^{3}} + \left(\frac{1}{2} \cdot \frac{1}{4} \cdot \frac{8}{6} \cdot \frac{5}{8} \cdot \frac{7}{10} \right) \left(\frac{1}{8} \cdot \frac{2}{5} \cdot \frac{4}{7} \right) \frac{r^{5}}{h^{5}} + \&c. \right\} :$$

then the discharge from the semicircle G, Fig. 7, with the diameter upwards and horizontal, is

(17.)
$$D = c_a \sqrt{2gh} \times 3.1416 \, r^2 (s_1 + s_2).$$

And the discharge from the semicircle 1, with the diameter downwards and horizontal, is

(18.)
$$D = c_d \sqrt{2gh} \times 3.1416 r^2 (s_1 - s_2).$$

If we put A for the area, we shall also have for the discharge from a circle H,

(19.)
$$D = c_d \sqrt{2gh} \times 2As_1.$$

In each of these three equations (17), (18), and (19), h is the depth of the centre of the circumference below the surface, and r the radius.

When the orifices rise to the surface, we have for the discharge from a semicircular notch G_o, with the diameter horizontal and at the surface,

(20.) $D = c_d \sqrt{2 g r} \times .9586 r^2 = c_d \sqrt{2 g r} \times .6103 A$; when the circumference of the semicircle is at the surface, and the diameter horizontal, as at I_o,

(21.)
$$D = c_d \sqrt{2gr} \times \frac{4}{15} (\sqrt{128} - 7) r^2 = c_d \sqrt{2gr} \times .7324 A$$
; when the horizontal diameter of the semicircle is uppermost, and at the depth r below the surface,

(22.) $D = c_d \sqrt{2 g r} \times 1.8667 r^2 = c_d \sqrt{2 g r} \times 1.1884 A$; and when the circumference of the entire circle is at the surface, as at H_0 ,

(23.)
$$D = c_d \sqrt{2gr} \times 3.0171 r^2 = c_d \sqrt{2gr} \times .9604 A.$$

If we desire to reduce equations (20), (21), and (22), to others in which the depth h of the centre of gravity from the surface is contained, we have only to substitute $\frac{h}{4244}$ for r in equation (20), and we shall get, for the discharge from a semicircle with the diameter at the surface,

(24.)
$$D = c_d \sqrt{2gh} \times .0367 A$$
:

also, by substituting $\frac{h}{.5756}$ for r in equation (21), we get, for the discharge from a semicircle when the circumference is at the surface and the diameter horizontal,

(25.)
$$D = c_d \sqrt{2gh} \times .9653 A$$
;

and when the horizontal diameter is uppermost, and at the depth r below the surface $r = \frac{h}{1.4244}$ and

(26.)
$$D = c_d \sqrt{2gh} \times .9957 A.$$

As a stands for the area of the particular orifice in each of the preceding expressions for the discharge, it must be taken of double the value, in equation (23) for instance where it stands for the area of a circle, that it is in equations (20), (21), or (23), where it represents only the area of a semicircle.

MEAN VELOCITY.

The mean velocity is easily found by dividing the area into the discharge per second given in the preceding equations. For instance, the mean velocity in the example represented in equation (9), is equal $\frac{2}{3}c_{\rm d}\sqrt{2g\,d}$, which is had by dividing the area ld into the discharge; and in like manner the mean velocity in equation (23) is 9604 $c_{\rm d}\sqrt{2g\,r}$.

PRACTICAL REMARKS ON THE DISCHARGE FROM CIRCULAR ORIFICES.

It has been shown, equation (19), that, for the discharge from a circle, we have

$$D = c_d \sqrt{2gh} \times 2As_1,$$

in which h is the depth of the centre, h the area, and s_1 the sum of the series

$$\left\{\frac{1}{2} - \left(\frac{1}{2} \cdot \frac{1}{4}\right) \left(\frac{1}{2} \cdot \frac{1}{4}\right) \frac{r^2}{h^2} - \left(\frac{1}{2} \cdot \frac{1}{4} \cdot \frac{3}{6} \cdot \frac{5}{8}\right) \left(\frac{1}{2} \cdot \frac{1}{4} \cdot \frac{3}{6}\right) \frac{r^4}{h^4} - \&c.\right\}:$$

and it has also been shown, equation (23), that, when the circumference touches the surface, this value becomes

$$D = c_d \sqrt{2gr} \times .9604 A.$$

Now when h is very large compared with r, it is easy to perceive that $2s_1 = 1$, and hence

(27.)
$$\mathbf{p} = c_{\mathbf{d}} \sqrt{2gh} \times \mathbf{A}.$$

(28.)
$$h = r, \text{ that } D = c_d \sqrt{2gh} \times .960 \text{ A};$$

$$h = \frac{5r}{4}, \text{ , } D = c_d \sqrt{2gh} \times .978 \text{ A};$$

$$h = \frac{8r}{2}, \text{ , } D = c_d \sqrt{2gh} \times .985 \text{ A};$$

$$h = \frac{7r}{4}, \text{ , } D = c_d \sqrt{2gh} \times .989 \text{ A};$$

$$h = 2r, \text{ , } D = c_d \sqrt{2gh} \times .992 \text{ A};$$

$$h = 3r, \text{ , } D = c_d \sqrt{2gh} \times .996 \text{ A};$$

$$h = 4r, \text{ , } D = c_d \sqrt{2gh} \times .998 \text{ A};$$

$$h = 5r, \text{ , } D = c_d \sqrt{2gh} \times .9987 \text{ A};$$

$$h = 6r, \text{ , } D = c_d \sqrt{2gh} \times .9991 \text{ A}.$$

These results show very clearly that, for circular orifices, the common expression for the discharge $c_d \sqrt{2gh} \times A$ is abundantly correct for all depths

exceeding three times the diameter, and that for lesser depths the extreme error cannot exceed four per cent. in reduction of the quantity found by this formula. We shall show, hereafter, when discussing the value of c_a , that from the sinking of the surface, and perhaps other causes, the discharge at lesser depths is even larger than that exhibited by the expression $c_d \sqrt{2gh} \times A$, the value of the coefficient of discharge, c_d , being found to increase as the depths h decrease. In fact, the sides of the orifice, the rounding of the arrises, and the depth and position with reference to the sides of the vessel, and surface of the water, are of far greater practical importance than extreme accuracy in the mathematical formula.

PRACTICAL REMARKS ON THE DISCHARGE FROM RECTANGULAR OBJICES.

It has been shown, equation (6), that the discharge from rectangular orifices, with two sides parallel to the horizon or surface of the water, is expressed by the equation

$$D = c_d \times \frac{2}{8} \sqrt{2 g} \times l \{h_b^{\frac{3}{2}} - h_t^{\frac{3}{2}}\},$$

in which l is the horizontal length of the orifice, h_b the depth of water on the lower, and h_t the depth on the upper, side. As it is desirable in practice to change this form into a more simple one, in which the height h of the centre and depth d of the orifice only shall be included, we then have $h_b = h + \frac{d}{a}$ and

 $h_t = h - \frac{d}{2}$. By substituting these values of h_b and h_t in the foregoing equations, and developing the result into a series, the terms of which, after the third, may be neglected, and putting A for the area l d, we shall find,

(29.)
$$D = c_a \sqrt{2gh} \times A \left\{1 - \frac{d^2}{96h^2}\right\}$$
 very nearly.

We have therefore for the accurate theoretical discharge

(30.)
$$D = c_d \sqrt{2gh} \times \frac{2}{8} A \left\{ \frac{(h + \frac{1}{2}d)^{\frac{3}{2}} - (h - \frac{1}{2}d)^{\frac{3}{2}}}{dh^{\frac{1}{2}}} \right\};$$

for the approximate discharge

$$D = c_d \sqrt{2gh} \times A \left\{ 1 - \frac{d^2}{96h^2} \right\};$$

and for the discharge by the common formula

$$D = c_{\mathbf{d}} \sqrt{2 g h} \times \mathbf{A}.$$

When the head (h) is large compared with (d) the height of the orifice, each of the three last equations gives the same value for the discharge; but as the common expression $c_d \sqrt{2gh} \times A$ is the most simple; and as the greatest possible error in using it for lesser depths does not exceed six per cent., viz. when the orifice rises to the surface and becomes a notch, it is evidently that formula best suited for practical purposes. The following table and equations will show more clearly the differences in the results as obtained from the true, the approximate, and the common formulæ, applied to "lesser" heads; and they will also explain, to some extent, why "coefficients" determined from the common formula, and that used by Poncelet and Lesbros, should decrease as the orifice approaches the surface.

(31.)3 $h = \frac{d}{2}$, $D = c_d \sqrt{2gh} \times .9428 A$. $D = c_d \sqrt{2gh} \times .9583 A$. \times .9733 A. "×·9693 A. "" $h = \frac{8d}{4}$, , , ", $\times .9796$ ", "× ·9815 A. $, \times 9854 \, \text{A}.$ "×·9864 A. h = d ,, ,, "×.9896A. " × ⋅9890 A. " " $h=\frac{8d}{9}, , , ,$ "×.9953 A. "" "×.9954A. "×·9974A h=2d, ,, ,, $, \times .9974 A.$ $h=\frac{5d}{2}, , , ,$ "×:9983 A· "×·9983A., h = 3 d, , , ,"×·9988A. "×.9988A. ", $h=\frac{7d}{\circ}, , , ,$ "×:9991 A. $", \times .9991$ A. ", ""×·9994 A. "" $\times .9994$ A. h=4d, ,, ,h=10d, ..., $", \times .9999 A.", "$ × .9999 A. ,,

In the foregoing Table the first column contains the head at the centre of the orifice expressed in parts of its height d; the second contains the values of the discharges according to equation (30); and the third column contains the approximate values determined from equation (29), the results in which are something larger than those in column 2, derived from the correct formula. The numerical coefficients of A, at every depth, are less in both than one, the constant coefficient according to the common formula. The latter, therefore (as in circular orifices), gives results exceeding the true ones, but the excess is in-

appreciable at greater depths than h = 3d, and for lesser depths than this the error cannot exceed six per cent. It may be useful to remark here, that when the orifice rises to the surface and becomes a notch, the "centre of mean velocity" is at four-ninths of the depth, and the centre of gravity at two-thirds of the depth from the surface. The former fraction is the square of the latter.

SECTION III.

EXPERIMENTAL RESULTS AND FORMULÆ.—COEFFICIENTS
OF DISCHARGE.

We have heretofore dwelt but very partially on the numerical values of the general coefficient of discharge In order to determine its value under different circumstances more particularly, it will be now necessary to consider some of the experiments which have been made from time to time. These do not always give the same results, even when conducted under the same circumstances and by the same parties, and there appears to exist a certain amount of error, more or less, inseparable from the subject. The experiments with orifices in thin plates afford the most consistent results: but even here the differences are sometimes greater than might be expected. many of the earlier experiments the value of the coefficient c_a comes out too large, which arises, very probably, from the orifices experimented with not being in thin plates, and partaking, more or less, of the nature of short tubes or mouth-pieces with rounded

arrises, which, we shall see, give larger coefficients than simple orifices. When an orifice is in the bottom of a vessel, it would appear more correct to measure the head from the surface to the vena-contracta than from the surface to the orifice itself; and as any error in measuring the head in any experiment must affect the value of the coefficient derived from such experiment, so as to increase it when the error is to make the head less, and vice versa, it appears that heads measured to an orifice in the bottom of a vessel, and not to the vena-contracta, must give larger coefficients from the experimental results than, perhaps, the true ones. The coefficients in the following pages have been almost all arranged and calculated, by the writer, from the original experiments.

In 1739 Dr. Bryan Robinson made some experiments on the discharge through small circular orifices, from one-tenth to eight-tenths of an inch in diameter, with heads of two and four feet, which give the following coefficients.

COEFFICIENTS	FROM	DR.	в.	BOBINSON'S	EXPERIMENTS.
--------------	------	-----	----	------------	--------------

Heads.	$\frac{1}{10}$ inch diameter.	$\frac{4}{10}$ inch diameter.	$\frac{5}{10}$ inch diameter.	$\frac{8}{10}$ inch diameter.
2 feet head	·768	-767	·761	·728
4 feet head	·7 6 8	·774	-765	·742

These results are pretty uniform, and the values from which they are derived are said to be "means taken from five or six experiments;" as values of c_d they are, however, too high. The apparatus made use of is not described; but it is probable, from the

[•] Helsham's Lectures, p. 390. Dublin, 1739.

results, that the plate containing the hole or orifice was of some thickness, and that the inner arris was slightly rounded. There is here, however, a very perceptible increase in the coefficients for the smaller orifices, but none for the smaller depth.

In a paper in the Transactions of the Royal Irish Academy, vol. ii. p. 81, read March 1st, 1788, Dr. Mathew Young determines the value of the coefficient for an orifice $\frac{3}{10}$ inch in diameter, with a mean head of 14 inches, to be 623. The manner in which this value is determined is very elegant, viz. by comparing the observed with the theoretical time of the water, in the vessel, sinking from 16 inches to 12 inches.

The following experiments by Michelotti, with circular orifices from 1 to about 3 inches diameter, and with from 6 to 23 feet heads, give for the mean value $c_d = .613$; and for square orifices of from 1 to 9 square inches in area, at like depths, the mean value of $c_d = .628$. The experiments are given in French feet and inches, according to which standard we have, in feet, $D = 7.77 \text{ A} \sqrt{h} \times t$, t being the time in seconds.* As the time of discharge in these ex-

^{*} The value of $\sqrt{2gh}$, equation (1), for measures in French feet, is $7.77\sqrt{h}$, and for measures in French inches, $26.9\sqrt{h}$, g being equal to 30.2 feet, or 362.4 inches, French measure. One French foot is equal to 1.06578 English feet, and the inches preserve the same proportion. The resulting coefficients must be the same, whatever standards we make our calculations from. Many of the most valuable formulæ and experiments in hydraulics are given in French measures of the old style. As our object, however, in the present section, is simply to determine from experiment the relation of the experimental to the theoretical discharge, it is not necessary to reduce the experiments to other measures than those in the original; but the value of the force of

periments varies from ten minutes to an hour, and as the depths are considerable, the results must be looked upon as pretty accurate; and it is worthy of note that here the coefficients are larger for square than for circular orifices.

We may remark here in passing how universal the coefficients .613 to .628 are for all forms of orifices in thin plates, or with the outside arrises chamfered. Indeed, we may always use the coefficient .62 with certainty, for practical purposes, for every orifice of this kind, whether at the surface in the form of a notch, or at the sides or bottom of a vessel, if the section of the approaching water be large in proportion to the area of the discharging orifice or notch. By coefficient we of course here mean that decimal which, multiplied by the theoretical value, gives the practical result; and this is substantially the same for notches and orifices sunk below the surface, as will appear farther on. There appears to us, however, an utter want of accuracy in using the coefficient 62 or thereabouts in gauging for all orifices, weirs included, no matter what the thickness or form of the orifice or crest of a weir may be, or area of the approaching channel. These will cause the coefficient to vary from 5 to 1 or more, and hence the necessity for endeavouring to reduce this portion of our subject to rule.

gravity, g, must, of course, be taken in those measures with which the experiments were made. In the French decimal, or modern style, the metre is equal to 3.2809 English feet, or 39.371 inches. The tenth part of a metre is the decimetre, and the tenth part of the decimetre 1 the centimetre, as the names imply. Table XIV. contains the weights and measures in general use in Great Britain and France, with their general ratios to each other.

The experiments made by the Abbé Bossut, contained in the following table, give the mean value of c_d , for both circular and square orifices, equal to ·616 nearly; and it may be perceived that, for the small depth in the last experiment, the coefficient rises so high as ·649. These and other experiments led the

approaches the surface, from ·617 to ·621; and at lesser depths than 1 foot other experiments show an increase in the coefficient up to ·650. The experiments of Poncelet and Lesbros show, however, a reduction in the coefficients for square orifices 8"×8" as they approach the surface from ·601 to ·572.

Brindley and Smeaton's experiments, with an orifice 1 inch square placed at different depths, give a mean

CORFFICIENTS CALCULATED FROM BRINDLEY AND SMEATON'S EXPERIMENTS.

- 1 foot head: orifice 1"×1": coefficient .639. 2 feet head: orifice 1"×1": coefficient .635
- 3 feet head: orifice 1"×1": coefficient .648 mean .637.
- 4 feet head: orifice 1" × 1": coefficient .632

from 1 foot to 4 feet, and of diameters from $\frac{1}{4}$ inch to 1 inch, give the following coefficients. Here the increase in the coefficients for lesser orifices and at lesser depths exhibits itself very clearly, notwithstanding a few instances to the contrary. The mean value of the coefficient c_4 derived from the whole, is .635. For small rectilineal orifices the coefficients were as follows:—

The most valuable series of experiments of which we are possessed are those made at Metz, by Poncelet and Lesbros. They were made with orifices 8 inches wide, nearly, and of different vertical dimensions placed at various depths down to 10 feet. The discrepancies as to any general law in the relation of the different values of the coefficient of discharge c_d

to the size and depth of the orifice in the preceding experiments, have been remedied to a great extent by these. They give an increase of the coefficients for the smaller and very oblong orifices as they approach the surface, and a decrease under the same circumstances in those for the larger square and oblong orifices. There are a few depths where maximum and minimum values are obtained: we use the terms "maximum and minimum values" for those which are greater in the one case and less in the other than the coefficients immediately before and after them, and not as being numerically the greatest or least values in the column. We have marked with a *, in the arrangement of the coefficients, Table I., these maximum and minimum values. The heads given in this table were measured to the upper side of the orifices, and by adding half the depth (d) to any particular head, we shall obtain the head at the centre.

As a perceptible sinking of the surface takes place in heads less than from five to three times the depth of the orifice, the coefficients are arranged in pairs, the first column containing the coefficients for heads measured from the still water surface some distance back from the orifice, and the second obtained when the lesser heads, measured directly at the orifice, were used. A very considerable increase in the value of the coefficients for very oblong and shallow small orifices, may be perceived as they approach the surface, and the mean value for all rectilinear orifices at considerable depths, seems to approach to .605 or .606.

We have shown, equation (29), that the discharge is

$$D = c_d \times \left\{1 - \frac{d^3}{96 h^2}\right\} \times A \sqrt{2g h},$$

approximately, in which expression d is the depth of the orifice, and h the head at its centre. Now it is to be observed, that it is not the value of c_d simply, which is given in Table I., but the value of $c_d \times \left\{1 - \frac{d^3}{96 h^2}\right\}$, the coefficient of A $\sqrt{2gh}$, equation (29).

The coefficients in the table are, therefore, less than the coefficients of discharge, strictly so called, by a quantity equal to $\frac{c_d d^2}{96 h^2}$. The value of this expression

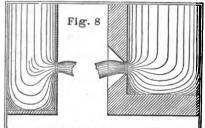

is in general very small, and it is easy to perceive from the first of the expressions in equation (31), p. 62, that it can never exceed 4.2 per cent., or more correctly .0417 in unity. If we wish to know the discharge from an orifice 4 inches square = $4'' \times 4''$, with its centre 4 feet below the surface, which is equivalent to a head of 3 feet 10 inches at the upper side, we find from the table the value of $c_d \left\{1 - \frac{d}{96 \ h^2}\right\} = .601$; hence we shall get

$$D = .601 \times A \sqrt{2gh} = .601 \times \frac{1}{9} \times 8.025 \times 2 =$$

$$\cdot 601 \times \frac{1}{9} \times 16 \cdot 05 = \frac{1}{9} \times 9 \cdot 646 = 1 \cdot 072$$

cubic feet per second. In the absence of any experiments with larger orifices, we must, when they occur, use the coefficients given in this table; and, in order to do so with judgment, it is only necessary to observe the relations of the sides and heads. For example, if the size of an orifice be 16"×4", we must

seek for the coefficient in that column where the ratio of sides is as four to one, and if the head at the upper side be five times the length of the orifice, we shall find the coefficient '626, which in this case is the same for depths measured behind, or at the orifice. For lesser orifices, the results obtained from the experiments of *Michelotti* and *Bossut*, pages 67 and 68, are most applicable; and also the coefficients of *Rennie*, page 71. It is almost needless to observe, that all these coefficients are only applicable to orifices in thin plates, or those

having the outside arrises chamfered as in Fig. 8. Very little dependence can be placed on calculations of the quantities of water discharged from

other orifices, unless where the coefficients have been already obtained by experiment or correct inference for them. If the inner arris next the water be rounded, the coefficient will be increased.

NOTCHES AND WEIRS.

We have already given some coefficients, pages 69 and 70, derived from the experiments of Du Buât, Brindley and Smeaton, and Poncelet and Lesbros, for finding the discharge over notches in the sides of large vessels; and it does not appear that there is any difference of importance between these and those for orifices sunk some depth below the surface, when the proper formula for finding the discharge for each

is used. If we compare Poncelet and Lesbros' coefficients for notches, page 70, with those for an orifice at the surface, TABLE I., we perceive little practical difference in the results, the head being measured back from the orifice, unless in the very shallow depths, and where the ratio of the length to the depth exceeds five to one. The depths being in these examples less than an inch, it is probable that the larger coefficients found for the orifice at the surface, arise from the upper edge attracting the fluid to it and lessening the effects of vertical contraction, as well as from less lateral contraction. Indeed, the results obtained from experiments with very shallow weirs, or notches, have not been at all uniform, and at small depths the discharge must proportionably be more affected by movements of the air and external circumstances than when the depths are considerable. We shall see that in Mr. Blackwell's experiments the coefficient obtained for depths of 1 and 2 inches was 676 for a thin plate 3 feet long, while for a thin plate 10 feet long it increased up to .805.

The experiments of Castel, with weirs up to about 30 inches long, and with variable heads of from 1 to 8 inches, lead to the coefficient $\cdot 497$ for notches extending over one-fourth of the side of a reservoir; and to the coefficient $\cdot 664$ when they extend for the whole width. For lesser widths than one-fourth, the coefficients decrease down to $\cdot 584$; and for those extending between one-third of, and the whole width, they increase from $\cdot 600$ to $\cdot 665$ and $\cdot 680$. Bidone finds $c_4 = \cdot 620$, and Eytelwein $c_4 = \cdot 635$. It will be

perceived from these and the foregoing results, that the third place of decimals in the value of c_4 , and even sometimes the second, is very uncertain; that the coefficient varies with the head and ratio of the notch to the side in which it is placed; and we shall soon show that the form and size of the weir, weirbasin, and approaches, still further modify its value.

When the sides and edge of a notch increase in thickness, or are extended into a shoot, the coefficients are found to reduce very considerably; and for small heads, to an extent beyond what the increase of resistance, from friction alone, indicates. Poncelet and Lesbros found, for orifices, that the addition of a horizontal shoot, 21 inches long, reduced the coefficient from .604 to .601, with a head of 4 feet; but for a head of only 4½ inches, the coefficient fell from .572 to .483, the orifice being $8'' \times 8''$. For notches 8 inches wide, with a horizontal shoot 9 feet 10 inches long, the coefficient fell from .582 to .479, for a head of 8 inches; and from ·622 to ·340, for a head of only 1 inch. Castel found also, for a notch 8 inches wide with a shoot 8 inches long attached and inclined at an angle 4° 18', that the mean coefficient for heads from 2 to 41 inches was only 527. Little dependence can be placed on experimental results obtained for shoots which partake of the nature of short pipes, and should be treated in like manner to find the discharge.*

We have obtained the following table of coefficients from some experiments made by Mr. Ballard, on the river Severn, near Worcester, "with a weir 2 feet

^{*} Civil Engineer and Architect's Journal for 1851, p. 647.

[†] Civil Engineer and Architect's Journal for 1851, pp. 642 and 645.

"The overfall bar was a cast-iron plate 2 inches thick, with a square top." The length of the overfall was 10 feet. The heads were measured from still water at the side of the reservoir, and at some distance up in it. The area of the reservoir was 21 statute perches, of an irregular figure, and nearly 4 feet deep on an average. It was supplied from an upper reservoir, by a pipe 2 feet in diameter and of 19 feet fall; the distance between the supply and the weir was about 100 feet. The width of the

reservoir as it approached the overfall was about 50 feet, and the plan and section, Fig. 9, of the weir and overfall in connection with it, will give a fair idea of the circumstances attending the experiments. For heads over 5 inches the velocity of approach to the weir was "perceptible to the eye," though its amount was not determined. We perceive that the coefficient (derived from two experiments) for a depth of 8 inches is '802, while the coefficient (derived from three experiments) for a depth of 722 inches is

·717, and for depths from 8 to 814 inches the mean coefficient is ·743: as all the attendant circumstances appear the same, these discrepancies and others must arise from the circumstances of the case: perhaps the supply, and, consequently, the velocity of approach, was increased while making one set of experiments, without affecting the still water near the side where the heads appear to have been taken. By comparing the results with those obtained by one of the same experimenters, Mr. Blackwell, on the Kennet and Avon Canal, we shall immediately perceive that the velocity of approach, and every circumstance which tends to alter and modify it, has a very important effect on the amount of the discharge, and, consequently, on the coefficient.

The experiments made by Mr. Blackwell, on the Kennet and Avon Canal, in 1850*, afford very valuable instruction, as the form and width of the crest were varied, and brought to agree more closely with actual weirs in rivers than the thin plates or boards of earlier experimenters. We have calculated and arranged the coefficients in the following table from these experiments. The variations in the values for different widths of crest, other circumstances being the same, are very considerable; and the differences in the coefficients, at depths of 5 inches and under, for thin plates and crests 2 inches wide, are greater than mere friction can account for; and greater also than the differences at the same depths between the coefficients for crests 2 inches thick, and 3 feet long.

* Civil Engineer and Architect's Journal, 1851, p. 642.

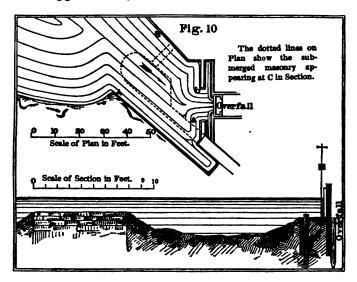

When more than one experiment was made with the same head, and the remilts were pretty uniform, the resulting coefficients are marked with a *. The effect of the converging wing-boards is very strongly marked. CORPFICIENTS FOR THE DISCHARGE OVER WEIRS, ARRANGED AND DERIVED FROM THE EXPERIMENTS OF MR. BLACKWELL.

† The discharge per second varied from .461 to .665 cubic feet in two experiments. The coefficient .435 is derived from the mean value.

The plan and section, Fig. 10, will give a fair idea of the approach to, and nature of the overfall made

use of in these experiments. The area of the reservoir was 2A. 1R. 30P., and the head was measured from the surface of the still water in it, which remained unchanged between the beginning and end of each experiment. The width of the approach AB from the reservoir was about 32 feet: the width at ab about 13 feet, below which the waterway widened suddenly, and again narrowed to the length of the The depth in front of the dam appears to overfall. have been about 3 feet; the depth on the dam, next the overfall, about 2 feet; and the depth on the sunk masonry in the channel of approach, about 18 inches. Altogether, the circumstances were such as to increase the amount of resistances between the reservoir, from which the head was measured, and the overfall, particularly for the larger heads, and we accordingly see that the coefficients become less for heads over six inches, with a few exceptions. The measurements of the quantities discharged appear to have been made very accurately, yet the discharges per second, with the same head and same length of overfall, sometimes vary; for instance, with the plank 2 inches thick and 10 feet long, the discharge per second for 4 inches head varies from 6.098 cubic feet to 6.491 cubic feet, or by about one-sixteenth of the whole quantity. Most of the results, however, are means from several experiments. The quantities discharged varied from one-tenth of a cubic foot to 22 cubic feet per second, and the duration of the experiments from 24 to 420 seconds. If we compare the coefficients for a plank 10 feet long and 2 inches thick in the foregoing table with those for the same overfall at Chew-Magna, we shall immediately perceive how much the form of the approaches affects the discharge. Indeed, were the area of the reservoir at Chew-Magna even larger than that for the Kennet and Avon experiments, it would be found, notwithstanding, that the coefficients in the former would still continue the larger, though not fully as large as those found under the particular circumstances.*

* There is a very important omission in all the preceding experiments on weirs and notches. In Fig. 10, for instance, it would have been necessary to obtain the heads at A B and ab in each experiment, above the crest, and also the head on and a few feet above the crest itself. These are, perhaps, best calculated by means of the observed velocity of approach. They would indicate the resistances at the different passages of approach, and enable us to calculate the coefficients correctly, and thereby render them more generally applicable to practical purposes. The coefficients

The following table gives the mean results of 88 experiments made by Francis, at the Lower Lock, Lowell, Massachusetts, in 1852. The duration of each of these experiments varied from 180 to 822 seconds. The coefficients in column 10 have been

calculated by ourselves, and the other results condensed from the large table given in Francis' Book.*

in the two previous tables are not as valuable as they otherwise would be from this omission. The level of still water near the banks is below that of the moving water in the current, therefore, heads measured from still water must give larger coefficients than if taken from the centre of the current. This may account, to some extent, for the larger coefficients in the first table, but apart from this, the short contracted channel immediately above the water-fall, Fig. 9, must increase the coefficients.

^{*} Lowell Hydraulic Experiments. New York, 1855.

The heads given in the 6th column are those which would give the observed discharge from the formula

$$D = \frac{2}{3} c_{d} (2g)^{\frac{1}{3}} h'^{\frac{3}{2}}.$$

As we have also equation (39)

$$D = \frac{2}{3} c_{\rm d} l(2g)^{\frac{1}{2}} \times \{ (h + h_{\rm a})^{\frac{3}{8}} - h_{\rm a}^{\frac{3}{9}} \}$$

we must, therefore, have

$$h' = \{(h+h_s)^{\frac{3}{2}} - h_s^{\frac{3}{2}}\}^{\frac{2}{3}},$$

the values of which are given in column 6. The values of h'' in column 8 are those which would be found by resolving the equation

$$D = C(l + \cdot 1 n h'') h''^{\frac{3}{2}}$$

n being the number of end contractions, and c a multiplier varying from 3.32 to 3.36.

In this table the theoretical head $\frac{v_a^2}{2g} = 0155 v_a^2$ due to the velocity of approach has been used and does not exceed 02 of a foot. We are of opinion, however, that the head is much greater, and should be taken $= \frac{v_a^2}{c_a^2 \times 2g} = 04 v_a^2$ or thereabouts. This would reduce the values of the coefficient of discharge c_a in the 10th column. The differences between h, h', and h'' in columns 3, 6, and 7 are here, practically, of little moment, and the value of c_a in column 10 would be nearly the same derived from either. The crest of the weir experimented upon was 1 inch thick. The weir measuring 10 feet \times 13 inches \times 1 inch, the top was rounded off at both arrises, leaving the central horizontal portion one quarter of an inch wide. The general result of these experiments verifies the

ordinary coefficient for notches in thin plates from $\cdot 617$ to $\cdot 628$ for the value of c_a .

Professor Thomson's experiments with rightangled triangular notches, in thin plates, give a mean coefficient of '617. Vide Note p. 55.

HEAD, AND FROM WHENCE MEASURED.

By referring to Table I., we shall see that there is a difference in the coefficients as obtained from heads measured on or above the orifice. This difference is greater in notches, or weirs, than in orifices sunk below the surface; and when the crest of a weir is of some width, the depths upon it vary. In the Kennet and Avon experiments, the heads measured from the surface of the water in the reservoir, and the depths at the "outer edge" (by which we understand the lower edge) of the crest were as follows:—

No intermediate heads are given, but those registered point out very clearly the great differences which often exist between the heads measured on a weir, or notch, and those measured from the still water above it: and how the form of the weir itself, as well as the nature of the approaches, alters the depth passing over. On a crest 2 feet wide, with 141 inches depth on the upper edge, we have found that the depth on the lower edge is reduced to 11½ inches, or as 1.26 to 1. The head taken from 3 to 20 feet above the crest, where the plane of the approaching water surface becomes curved, is that in general which is best suited for finding the discharge by means of the common coefficients, but a correct section of the channel and water-line, showing the different depths upon and for some distance above the crest, is necessary in all experiments for determining accurately by calculation the value of the coefficient of discharge $c_{\rm d}$.

Du Buât, finding the theoretical expression for the discharge through an orifice of half the depth h,

$$D = \frac{2}{8} \sqrt{2g} \times l \left\{ h^{\frac{3}{3}} - \left(\frac{h}{2}\right)^{\frac{3}{3}} \right\},\,$$

equation (6)

$$= \frac{2}{8} lh \sqrt{2gh} \times \left\{ 1 - \left(\frac{1}{2}\right)^{\frac{3}{2}} \right\} = 646 \times \frac{2}{8} lh \sqrt{2gh},$$

to agree pretty closely with his experiments, seems to have assumed that the head h is reduced to $\frac{h}{2}$ in passing over. This is a reduction, however, which never takes place unless with a wide crest and at its lower edge, or where the head h is measured at a

considerable distance above the weir, and when a loss of head due to the distance and obstructions in channel takes place. When there is a clear weir basin immediately above the weir, we have found that, putting h for the head measured from the surface in the weir basin, and h_w for the depth on the upper edge of the weir, that

$$(32.) h - h_{\rm w} = 14\sqrt{h},$$

for measures in feet, and

$$(33.) h-h_{\star} = \cdot 48 \sqrt{h},$$

for measures in inches. The comparative values of h and h_w depend, however, a good deal on the particular circumstances of the case. Dr. Robinson found* $h = 1 \cdot 111 h_w$, when h was about 5 inches. The expressions we have given are founded on the hypothesis, that $h - h_w$ is as the velocity of discharge, or as the \sqrt{h} nearly. For small depths, there is a practical difficulty in measuring with sufficient accuracy the relative values of h and h_w . Unless for very small heads the sinking will be found in general to vary from $\frac{h}{10}$ to $\frac{h}{4}$, and in practice it will always be useful to observe the depths on the weir as well as the heads for some distances (and particularly where the widths contract) above it.

In order to convey to our readers a more definite idea of the differences between the coefficients for heads measured at the weir, or notch, and at some distance above it, we shall assume the difference of the heads $h - h_w = \frac{h_w}{r}$; then $\frac{h_w}{h - h_w} = r$, and $\frac{1}{r} = \frac{h - h_w}{h}$,

* Proceedings of the Royal Irish Academy, vol. iv. p. 212.

hence
$$h = \frac{r+1}{r} h_w$$
 and $h_w = \frac{r}{r+1} h$.

Now the discharge may be considered as that which would take place through an orifice whose depth is h_w with a head over the upper edge equal to $h - h_w = \frac{h_w}{r}$; hence from equation (6) the discharge is equal to

$$\frac{2}{8} l \sqrt{2g} \times c_{\rm d} \left\{ h^{\frac{3}{2}} - \left(\frac{h_{\rm w}}{r}\right)^{\frac{3}{2}} \right\},\,$$

and substituting for $h_{u}^{\frac{3}{2}}$ its value $\left(\frac{r+1}{r}h_{w}\right)^{\frac{3}{2}}$, we shall find the value of

(34.)
$$D = \frac{2}{3} l h_{w} \sqrt{2 g h_{w}} \times c_{d} \left\{ \left(1 + \frac{1}{r} \right)^{\frac{3}{2}} - \left(\frac{1}{r} \right)^{\frac{3}{2}} \right\}.$$

As the value of the discharge would be expressed by

$$\frac{2}{8} l h_{\rm w} \sqrt{2 g h_{\rm w}} \times c_{\rm d}$$

if the head $h - h_w$ were neglected, it is evident the coefficient is increased, under the circumstances, from c_4 to

$$c_4 \times \left\{ \left(1 + \frac{1}{r}\right)^{\frac{3}{2}} - \left(\frac{1}{r}\right)^{\frac{3}{2}} \right\};$$

or, more correctly, the common formula has to be multiplied by $(1+\frac{1}{r})^{\frac{3}{2}}-(\frac{1}{r})^{\frac{3}{2}}$, to find the true discharge, and the value of this expression for different values of $\frac{1}{r}=n$ will be found in Table IV. If we suppose that

$$h-h_{\rm w}=\frac{h_{\rm w}}{10}$$
, then $\frac{1}{r}=\frac{1}{10}=n$;

and we find from the table $(1 + \frac{1}{r})^{\frac{3}{2}} - (\frac{1}{r})^{\frac{3}{2}} = 1.1221$.

Now if we take the value of c_d for the full head h to be .628, we shall find $1.1221 \times .628 = .705$, rejecting the latter figures, for the coefficient when the head is measured at the orifice; and if $\frac{1}{r} = \frac{2}{10} = n$, we should find in the same manner the new coefficient to be $1.2251 \times .628 = .769$ nearly. The increase of the coefficients determined, page 77, from Mr. Ballard's experiments is, therefore, evident from principle, as the heads were taken at the notch; and it is also pretty clear that, in order to determine the true discharge, the heads both on, at, and above a weir should be taken. Most of the discrepancies in the coefficients determined from experiment have arisen from imperfect and limited observations of the facts. Amongst these the velocity of approach should never be neglected by observers, as its effect on the discharge is often considerable in increasing the quantity. effect of the form of the weir and approaches is scarcely ever sufficiently considered by professional Most of the discussions which arose with reference to the gaugings on the Metropolitan Main Drainage Question would have been obviated if the calculators, or engineers, had taken into account the different circumstances attendant on it, instead of applying generally a formula suited to a particular case, namely, a thin crest, a small notch, and a large body of water immediately above it; and applied a correct formula for finding the effects of the velocity of approach.

The two following tables have been reduced to English measures of feet, from Boileau's experiments; they show the relation of the head to the depth on the crest at the upper arris. The coefficient for the head h being known, we may, from our equation (34), calculate that due to h on the weir.

Table showing the ratio of the head, h, to the depth, h_w , on a Plank Weir of the full width of the Channel, immediately at the upper edge, or $\frac{h}{h_w}$, see equation (33), when the sheet of water is free after passing over, with air under it.

If we were to use the head h_w instead of h, to calculate the discharge, when $\frac{h}{h_w} = 1.2$, then a coefficient of .628 for the head h would become .769 for the head h_w in equation (34): for $\frac{1}{r} = .2$, and, therefore, Table IV., $.628 \times (1.2)^{\frac{3}{2}} = .628 \times 1.2251 = .769$.

If we were to use the head h_w instead of h to calculate the discharge, when $\frac{h}{h_w} = 1.25$, then a coefficient of .628 for the head h would become .799 for the head h_w in equation (34): for $\frac{1}{r} = .25$; and, therefore, the value of $c_d \left\{ \left(1 + \frac{1}{r}\right)^{\frac{3}{2}} - \left(\frac{1}{r}\right)^{\frac{3}{2}} \right\}$, Table IV., is $.628 \times (1.25)^{\frac{3}{2}} - (.25)^{\frac{3}{2}} = .628 \times 1.2725 = .799$: and so on we may calculate the value of the coefficient to be applied to the depth h_w on the weir, for any other ratios between h and h_w by means of equation (34).

Boileau made some valuable experiments at Metz,

which were published in 1854. They give the following results for vertical plank weirs extending from side to side of the channel, when the water passed over without adhering to the crest:—

Height of weir over bot- tom of channel in feet.	Head above.	Mean coefficient.
$3\cdot$	·2 to 1·6	•645
1:3	·16 to ·5	·6 2 2
•6	·15 to ·25	·625

When the water passing over was joined to the crest, and no air between the sheet passing over and the water below the weir, the experiments gave

Height of weir over bot- tom of channel in feet.	He	ad above.	Mean coefficient.
$2 \cdot$	1.	to 1.6	·69 4
1:3	•6	to 1.8	·690
•6	•36	to 1:3	•675

When the plank weir leant up-stream 4 inches to a foot, the mean value of c_d was 620, the height of weir being 1.5 foot, and with heads from .23 to .5 foot. When its crest was rounded to a semi-cylinder, the coefficient was, with a head of .26 foot, .696, and with a head of .52 foot, .843; the water adhering to the crest. With a head of .6 foot the coefficient was .867, and with a head of .85 foot, .840, when the water passed over without air between it and the water below the crest. The following tables give the experimental and reduced coefficients for vertical plank weirs of different heights, and with different heads, when the water passes over in a full sheet, and also when it is joined to the crest and lower water. Also for plank weirs suitable for sluices, leaning up-stream with a slope of one-third horizontal to one vertical.

COEFFICIENTS of Vertical Plank Weirs at right angles to the Channel, when the edge is chamfered at the lower side, and when the water is free and not in contact with the slope, or water below; derived from Boileau's experiments.

The following table gives the result of experiments on chamfered plank weirs, for gauging, extending across a channel at right angles to it, when the backwater below was joined to the head-water at passing over, and when there was no air between:—

Height of weir over the bottom of the channel below... \\ \cdot 66 \cdot 83 \quad 1.00 \quad 1.16 \quad 1.82 \quad 1.48 \quad 1.65 \quad 2.00 \\ \text{Heads passing over the weir in each case, when absorbed at the crest into the back-water \\ \end{array} \cdot 23 \quad 31 \quad 38 \quad 45 \quad 51 \quad 55 \quad 56 \quad \cdot 92 \\ \end{array}

which shows that the head was drowned (noyée) when the depth of the lower channel below the crest of the weir was less than 2½ times the head passing over, taking a general average.

The effect of the form of the crest in increasing the coefficients is distinctly observable in this Table, although the weirs experimented on overhung the water above, between the crest and the bottom of the channel.

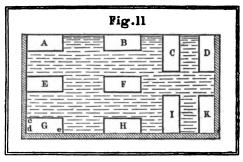

We must protest against the notation adopted by Boileau and Morin, of giving only two-thirds of the coefficient of discharge, c_d , for weirs, instead of the full and true value. The correct formula for the discharge from a weir is $D = \frac{2}{3}lh\sqrt{2gh}$. Now they assume a coefficient due to an incorrect formula $D = lh\sqrt{2gh}$, which reduces c_d to $\frac{2}{3}c_d$ to give the same final results. This leads also to an unnecessary distinction between the coefficients of orifices at the surface, or notches, and orifices sunk to some depth, which, practically, have the same, or nearly the same, general value.

SECTION IV.

VARIATIONS IN THE CORFFICIENTS FROM THE POSITION OF THE ORIFICE.—GENERAL AND PARTIAL CONTRACTION.—VELOCITY OF APPROACH.—PRACTICAL FORMULÆ FOR THE DISCHARGE OVER WEIRS AND NOTCHES.—CENTRAL AND MEAN VELOCITIES.

A glance at TABLE I. will show us that the coefficients increase as the orifices approach the surface, to a certain depth dependent on the ratio of the sides, and that this increase increases with the ratio of the length to the depth: some experimenters have found the increase to continue uninterrupted for all orifices up to the surface, but this seems to hold only for depths taken at or near the orifice when it is square or nearly so: it has also been found that the coefficient increases as the orifice approaches to the sides or bottom of a vessel: as the contraction becomes imperfect the coefficient increases. facts probably arise from the velocity of approach being more direct and concentrated under the respective circumstances. The lateral orifices A, B, C, D, E, F, G, H, I, and K, Fig. 11, have coefficients differing more or less from each other. The coefficient for a is found to be larger than either of those for B, C, E, or D; that for G or K larger than that for H or I; that for H larger than that for I; and that for F, where the contraction is general, least of The contraction of the fluid on entering the orifice F removed from the bottom and sides is complete; it is termed, therefore, "general contraction;" that at the orifices A, E, G, H, I, K, and D, is interfered with by the sides; it is therefore incomplete,

and termed "partial contraction." The increase in the coefficients for the same-sized orifices at the same

mean depths may be assumed as proportionate to the length of the perimeter at which the contraction is partial, or from which the lateral flow is shut off; for example, the increase for the orifice G is to that for H as cd+de:de; and in the same manner the increase for G is to that for H as Cd+de:de. If we put H for the ratio of the contracted portion Cde to the entire perimeter, and, as before, C_{d} for the coefficient of general contraction, we shall find the coefficient of partial contraction to be equal to

(35.) $c_d + \cdot 09 \, n = c_d + \cdot 1 \, n$ nearly, for rectangular orifices. The value of the second term $\cdot 09 \, n$ is derived from various experiments. If we assume $\cdot 617$ for the mean value of c_d , we may change the expression into the form $(1 + \cdot 146 \, n) \, c_d$. When $n = \frac{1}{4}$, this becomes $1 \cdot 036 \, c_d$; when $n = \frac{1}{4}$, it becomes $1 \cdot 073 \, c_d$; and when $n = \frac{3}{4}$, contraction is prevented for three-fourths of the perimeter, and the coefficient for partial contraction becomes $1 \cdot 109 \, c_d$. The form which we have given equation (35) is, however, the simplest; but the value of n must not exceed $\frac{3}{4}$. If in this case $c_d = \cdot 617$, the coefficient

for partial contraction becomes $.617 + .09 \times \frac{3}{4} = .617 + .067 = .684$. Bidone's experiments give for the coefficient of partial contraction $(1 + .152 n) c_d$; and Weisbach's $(1 + .132 n) c_d$.

VARIATION IN THE COEFFICIENTS FROM THE REFECTS OF THE VELOCITY OF APPROACH.

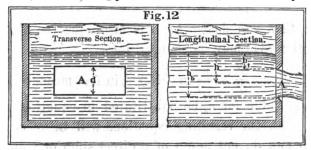

Heretofore we have generally supposed the water in the vessel to be almost still, its surface level unchanged, and the vessel consequently large compared with the area of the orifice. When the water flows to the orifice with a perceptible velocity, the contracted vein and the discharge are both found to be increased, other circumstances being the same. If the area of the vessel or channel in front exceed thirty times that of the orifice, the discharge will not be perceptibly increased by the induced velocity in the conduit; but for lesser areas of the approaching channel corrections due to the velocity of approach become necessary. It is clear that this velocity may arise from either a surface inclination in the channel, an increase of head, or a small channel of approach.

We get equation (6) for the discharge from a rectangular orifice A, Fig. 12, of the length *l*, with a head measured from still water

$$D = \frac{2}{3}c_4l\sqrt{2g} \times \{h_{\frac{1}{5}}^{\frac{3}{5}} - h_{\frac{1}{5}}^{\frac{1}{5}}\},$$

in which h_b and h_t are measured to the surface at some distance back from the orifice, as shown in the section. The water here, however, must move along the channel towards the orifice with considerable velocity. If A be the area of the orifice, and C the area of the

channel, we may suppose with tolerable accuracy that

this velocity is equal to $\frac{A}{C}v_o$, in which v_o represents the mean velocity in the orifice. If we also represent by v_a the velocity of approach, we get the equation

$$(36.) v_{a} = \frac{A}{C} \times v_{o},$$

and consequently the theoretical height (h_a) due to it is

(37.)
$$h_a = \frac{A^2}{C^2} \times \frac{v_o^2}{2g} = .0155 \frac{A^2 v_o^2}{C^2}$$
 in feet measures.*

The height h_a may be considered as an increase of head, converting h_b into $h_b + h_a$, and h_t into $h_t + h_a$. The discharge therefore now becomes

(38.)
$$D = \frac{2}{8}c_d l \sqrt{2g} \{ (h_b + h_a)^{\frac{2}{3}} - (h_t + h_a)^{\frac{2}{3}} \};$$

which, for notches or weirs, is reduced to

*When the approaching velocity passes through the orifice without contraction, it is evident that the head h_a required to produce that velocity, in the orifice with contraction, must be $h_a = \frac{A^2}{C^2} \times \frac{v_o^2}{2 g \times c_d^2}$ instead of $h_a = \frac{A^2}{C^2} \times \frac{v_o^2}{2 g}$, in which case equation (40) becomes $h_a = \frac{D^2}{C^2} \times \frac{1}{2 g c_d^2}$. In like manner we must have $h_a = \frac{v_a^2}{c_d^2 \times 2 g} = 0.04 v_d^2$ in feet measures when v_a is the velocity of approach and $c_d = 0.017$.

(39.)
$$D = \frac{2}{3} c_{d} l \sqrt{2g} \{ (h_{b} + h_{a})^{\frac{3}{4}} - h_{a}^{\frac{3}{4}} \},^{*}$$

as h, then vanishes. As D is also equa to $A \times v_o$, equation (37) may be changed into

(40.)
$$h_a = \frac{D^e}{C^2} \times \frac{1}{2 q} = .0155 \frac{D^2}{C^2}$$
 in feet measures.

If this value for h_a be substituted in equations (38) and (39), the resulting equations will be of a high order and do not admit of a direct solution; and in (38) and (39), as they stand, h_a involves implicitly the value of p, which we are seeking for. By finding at first an approximate value for the velocity of approach, the height h_a due to it can be easily found, equation (37); this height, substituted in equation (38) or (39), will give a closer value of p, from which again a more correct value of p, can be determined; and by repeating the operation the values of p and p can be had to any degree of accuracy. In general the values found at the second operation will be sufficiently correct for all practical purposes.

It has been already observed that, for orifices, it is advisable to find the discharge from a formula in which only one head, that at the centre, is made use of; and though TABLE IV., as we shall show, enables us to calculate the discharge with facility from either formula, it will be of use to reduce equation (38) to

^{*} The formula for the discharge over weirs, taking into account the velocity of approach, $D=2.95\ c_a\ l\sqrt{h}+.115\ v_a^2$, given by D'Aubuisson, Traité Hydraulique, seconde édition, pp. 78 et 95, and adopted by some English writers and engineers, is incorrect in principle. In feet measures it becomes $D=5.35\ c_a\ l\ h\times\sqrt{h}+.03494\ v_a^2$, which form,—with alterations in the numerals and measures,—was used for calculating discharges of sewers during the Metropolitan Main Drainage discussion.

a form in which only the head (h) at the centre is used. The error in so doing can never exceed six per cent., even at small depths, equation (31), and this is more than balanced by the observed increase in the coefficients for smaller heads.

The formula for the discharge from an orifice, h, being the head at the centre, is

$$D = c_d \sqrt{2 g h} \times A$$
;

and when the additional head h_a due to the velocity of approach is considered,

$$D = c_{d} \sqrt{2g(h + h_{a})} \times A,$$

which may be changed into

(41.)
$$D = A\sqrt{2g}h \times c_d \left\{1 + \frac{h_a}{h}\right\}^{\frac{1}{2}}$$

Equation (39), for notches, may be also changed to the form

(42.)
$$D = \frac{2}{3} A \sqrt{2 g h_b} \times c_d \left\{ \left(1 + \frac{h_b}{h_b} \right)^{\frac{3}{2}} - \left(\frac{h_a}{h_b} \right)^{\frac{3}{2}} \right\};$$

this is similar in every way to the equation

(43.)
$$D = \frac{2}{8} A \sqrt{2g d} \times c_4 \left\{ \left(1 + \frac{h_t}{d} \right)^{\frac{3}{2}} - \left(\frac{h_t}{d} \right)^{\frac{3}{2}} \right\},$$

for the discharge from a rectangular orifice whose depth is d, with the head h, at the upper edge.

Table III. contains the values of $\left\{1+\frac{h_a}{h}\right\}^{\frac{1}{2}}$ in equation

(41), and Table IV. the values of $(1 + \frac{h_a}{h_b})^{\frac{3}{2}} - (\frac{h_a}{h_b})^{\frac{3}{2}}$ in equation (42), or the similar expression in (43), $\frac{h_a}{h_b}$ or $\frac{h_t}{d}$ being put equal to n; and we perceive that the effect of the velocity of approach is such as to increase the coefficient from c_d to c_d $\{1 + \frac{h_a}{h}\}^{\frac{1}{2}}$ for orifices

sunk some distance below the surface, and into

$$c_{\rm d} \left\{ \left(1 + \frac{h_{\rm a}}{h_{\rm b}}\right)^{\frac{3}{8}} - \left(\frac{h_{\rm a}}{h_{\rm b}}\right)^{3} \right\}$$

for weirs when h is the height due to the velocity of approach, h the depth of the centre of the orifice, and h, the head on the weir. A few examples, showing the application of the formulæ (41), (42), and (43), and the application of TABLES I., II., III., and IV. to them, will be of use. We shall suppose, for the present, the velocity of approach v_{\bullet} to be given, and no extra head be required to maintain it through

the orifice: in other words when $h_a = \frac{v_a^2}{2a \times 956^2}$ $= .017 v_{\bullet}^2$ in feet measures nearly.

EXAMPLE I. A rectangular orifice, 12 inches wide by 4 inches deep, has its centre placed 4 feet below the surface, and the water approaches the head with a velocity of 28 inches per second; what is the discharge? For an orifice of the given proportions, and sunk to a depth nearly four times its length, we shall find from TABLE I.

$$c_4 = \frac{.616 + .627}{2} = .621$$
 nearly.

As the coefficient of velocity, equation (2), for water flowing in a channel is about 956, we shall find, column No. 3, Table II. the height $h_a=1\frac{1}{2}=1.125$ inch nearly, corresponding to the velocity 28 inches. Equation (41),

$$D = A\sqrt{2gh} \times c_d \left\{1 + \frac{h_a}{h}\right\}^{\frac{1}{2}},$$

now becomes

$$D = 12 \times 4 \sqrt{2gh} \times 621 \left\{ 1 + \frac{1.125}{48} \right\}^{\frac{1}{2}}.$$

We also find $\sqrt{2gh} = 192.6$ inches when h = 48 inches, Table II.; therefore

$$D = 12 \times 4 \times 192.6 \times .621 \left\{ 1 + \frac{1.125}{48} \right\}^{\frac{1}{2}}$$

=9244·8×·621{1+·0234}*=9244·8×·621×1·0116, (as {1·0234}*=1·0116 from Table III.)=9244·8×·628 nearly = 5805·7 cubic inches=3·36 cubic feet per second. Or thus: The value of ·621×(1·0234) being found equal ·628, $p=A\times$ ·628 $\sqrt{2g\times48}$. Now for the coefficient ·628, and h=48 inches, Table II. gives us ·628 $\sqrt{2g\times48}$ =120·96 inches; hence we get $p=12\times4\times120\cdot96=5806\cdot08$ cubic inches=3·36 cubic feet, the same as before, the difference ·38 in the cubic inches being of no practical value. If we find h_a from the formula $h_a=\frac{v_a^2}{2g\,c_a^2}=2\cdot6$ inches, then we shall get $p=3\cdot41$ cubic feet nearly.

If the centre of the orifice were within 1 foot of the surface, the effect of the velocity of approach would be much greater; for then

$$c_4 \times \left\{1 + \frac{h_*}{h}\right\}^{\frac{1}{2}} = \text{(from Table I.)} \cdot 623 \left\{1 + \frac{1 \cdot 125}{12}\right\}^{\frac{1}{2}}$$

$$= \text{(from Table III.)} \cdot 623 \times 1 \cdot 047 = \cdot 652 \text{ instead of } \cdot 628. \quad \text{In this case the discharge is } D = 12 \times 4 \times \cdot 652 \times 96 \cdot 3 \text{ (from Table II.)}$$

$$= 12 \times 4 \times 62 \cdot 8 = 3014 \cdot 4 \text{ cubic inches} = 1 \cdot 744 \text{ cubic feet per second.} \quad \text{Or we may find the value of } \cdot 652 \sqrt{2gh} \text{ directly from Table II. thus:}$$

The value of
$$.628 \sqrt{2g \times 12} = 60.48$$
 .628
The value of $.666 \sqrt{2g \times 12} = 64.14$.652
 38 : 3.66 : 24 : 2.31.
Hence $.652 \sqrt{2gh} = 60.48 + 2.31 = 62.79$, and the

discharge = $12 \times 4 \times 62.79 \times 3013.92$ cubic inches = 1.744 cubic feet per second, the same as before. If we take $h_a = \frac{v_a^2}{2 g c_d^2} = 2.6$ inches, we shall find p = 1.833 cubic feet nearly.

EXAMPLE II. A rectangular notch, 7 feet long, has a head of 8 inches measured at about 4 feet above the orifice, and the water approaches the head with a velocity of $16\frac{1}{4}$ inches per second; what is the discharge? For a still head we shall assume $c_4 = .628$ in this case, and we have from equation (42)

$$D = \frac{2}{3} A \sqrt{2 g h_b} \times c_d \left\{ \left(1 + \frac{h_a}{h_b} \right)^{\frac{3}{3}} - \left(\frac{h_a}{h_b} \right)^{\frac{3}{3}} \right\}$$

As in the last example, we shall find from TABLE II. (h_a) the height due to the velocity of approach $(16\frac{1}{4})$ inches) to be $\frac{3}{8} \equiv 0.375$ inch, assuming the coefficient of velocity to be .956. We have, therefore, $h_a \equiv .375$, $h_b \equiv 8$, $c_d \equiv .628$, and $A \equiv 7 \times 12 \times 8$, or for measures in feet $\frac{h_a}{h_b} \equiv .047$, $h_b \equiv \frac{2}{3}$, and $A \equiv 7 \times \frac{2}{3}$; hence

 $D = \frac{2}{8} \times 7 \times \frac{2}{8} \qquad 2g \times \frac{2}{8} \times \cdot 628 \left\{ (1\cdot047)^{\frac{3}{2}} - (\cdot047)^{\frac{3}{2}} \right\}.$ The value of $(1\cdot047)^{\frac{3}{2}} - (\cdot047)^{\frac{3}{2}}$ will be found from Table IV. equal to $1\cdot0612$; the value of $2g \times \frac{2}{8}$ will be found from Table II. equal to $6\cdot552$, viz. by dividing the velocity $78\cdot630$, to be found opposite 8 inches, by 12; hence

$$D = \frac{2}{3} \times 7 \times \frac{2}{3} \times 6.552 \times .628 \times 1.0612$$
$$= \frac{2}{3} \times 7 \times 4.368 \times .628 \times 1.0612$$

$$= \frac{2}{8} \times 7 \times 4.368 \times .666 \text{ nearly}$$
$$= \frac{2}{8} \times 7 \times 2.909 = 7 \times 1.939$$

= 13.573 cubic feet per second = 814.38 cubic feet per minute. Or thus: From Table VI. we find, when the coefficient is 628, the discharge from a weir 1 foot long, with a head of 8 inches, to be 109.731 cubic feet per minute. The discharge for a weir 7 feet long, when $\frac{h_a}{h} = .047$ is therefore $109.731 \times 7 \times 1.0612 = 815.12$ cubic feet per minute. The difference between this value and that before found, 814.38 cubic feet is immaterial, and has arisen from not continuing all the products to a sufficient number of places of decimals. If $h_a = \frac{v_a^2}{2 g c_d^2} = .87$ inch, then p = 14.51 cubic feet per second nearly.

We have, in equations (36) and (37), pointed out the relations between the channel, orifice, velocity of approach, and velocity in the orifice, viz.

$$v_{a} = \frac{\Lambda}{C} \times v_{o}$$
, and $h_{a} = \frac{\Lambda^{2}}{C^{2}} \times \frac{v_{o}^{2}}{2g} = \frac{D^{2}}{2g}$, in which $h_{a} = \frac{v_{a}^{2}}{2g}$ (neglecting, for the present, the coefficient of velocity in passing through the orifice). As v_{o} is the actual velocity in the orifice, $\frac{v_{o}}{c_{d}}$ must be the theoretical velocity due to the head $h + h_{a}$, and therefore

$$\begin{split} h + h_{\bullet} &= \frac{v_{\circ}^2}{c_{\rm d}^2 \times 2g}, \text{and } h = \frac{v_{\circ}^2}{c_{\rm d}^2 \times 2g} - \frac{v_{\bullet}^2}{2g}; \text{ hence} \\ \frac{h_{\bullet}}{h} &= \frac{1}{\frac{v_{\circ}^2}{v_{\bullet}^2 \times c_{\rm d}^2} - 1} = \frac{c_{\rm d}^2 v_{\bullet}^2}{v_{\circ}^2 + c_{\rm d}^2 v_{\bullet}^2} = \frac{c_{\rm d}^2 A^2}{c^2 - c_{\rm d}^2 A^2} \text{ for } \frac{v_{\circ}^2}{v_{\bullet}^2} = \frac{c^3}{A^2}. \end{split}$$

We have hence

(44.)
$$\frac{h_{a}}{h} = \frac{c_{d}^{2} \Lambda^{2}}{C^{2} - c_{d}^{2} \Lambda^{2}};$$

substituting this value in equations (41) and (42), there results

(45.)
$$\begin{cases} D = A \sqrt{2gh} \times c_d \left\{ 1 + \frac{c_d^2}{m^2 - c_d^2} \right\}^{\frac{1}{2}} \text{ or,} \\ D = A \sqrt{2gh} \times \frac{c_d}{\left(1 - \frac{c_d^2}{m^2} \right)^{\frac{1}{2}}}, \end{cases}$$

in which $m = \frac{Q}{A}$, for the discharge from an orifice at some depth, and for the discharge from a weir,

(46.)
$$D = \frac{2}{3} \Lambda \sqrt{2gh_b} \times c_d \left\{ \left(1 + \frac{c_d^2}{m^2 - c_d^2}\right)^{\frac{3}{2}} - \left(\frac{c_d^2}{m^2 - c_d^2}\right)^{\frac{3}{2}} \right\}$$

The two last equations give the discharge when the ratio of the channel to the orifice $\frac{C}{A} = m$ is known, and also when the whole quantity of water passing through the orifice, that due to the velocity of approach as well as that due to the pressure, suffers a contraction whose coefficient is c_4 . When $h_a = \frac{v_a^2}{2 \ a \times c_2^2}$, that

is when the velocity of approach v_* passes through the orifice without contraction, we shall get

$$\frac{h_a}{h} = \frac{v_a^2}{v_0^2 - v_a^2} = \frac{\Lambda^2}{C^2 - \Lambda^2} = \frac{1}{m^2 - 1},$$

consequently, in this case, equation (45) becomes

(45a.)
$$D = A \sqrt{2gh} \times c_4 \times \left\{1 + \frac{1}{m^2 - 1}\right\}^{\frac{1}{2}};$$

and equation (46) in like manner changes into

$$(46a.) \, \mathbf{D} = \frac{2}{8} \mathbf{A} \sqrt{2g h_b} \times c_4 \times \left\{ \left(1 + \frac{1}{m^2 - 1} \right)^{\frac{3}{2}} - \left(\frac{1}{m^2 - 1} \right)^{\frac{3}{2}} \right\}.$$

The last members of these two equations are the same as the like members in (45) and (46), when c_d , within the brackets = 1; consequently we shall easily find their values for the coefficient 1 in the last page of TABLE V., for the respective values of $m = \frac{C}{A}$; and also for those of $\frac{h_a}{h_b} = \frac{1}{m^2 - 1}$. When $c_d = 1$, equation (45) may be changed into

$$D = A \left\{ \frac{2gh}{1 - \left(\frac{1}{m}\right)^2} \right\}^{\frac{1}{2}}.$$

This is the equation of Daniel Bernoulli, and only a particular case of the one we have given.

If we put $n = \frac{c_d^2}{m^2 - c_d^3}$, the values of $\left\{1 + \frac{c_d^2}{m^2 - c_d^3}\right\}^{\frac{1}{2}}$, and of $\left\{1 + \frac{c_d^2}{m^2 - c_d^2}\right\}^{\frac{3}{2}} - \left\{\frac{c_d^2}{m^2 - c_d^2}\right\}^{\frac{3}{2}}$, respectively, can be easily had from Tables III. and IV. We have, however, calculated Tables V. for different ratios of the channel to the orifice, and for different values of the coefficient of discharge. This table gives at

$$c_{4} \left\{1 + \frac{c_{4}^{\sharp}}{m^{2} - c_{4}^{2}}\right\}^{\frac{1}{2}} \text{ and } c_{4} \left\{\left(1 + \frac{c_{4}^{2}}{m^{2} - c_{4}^{2}}\right)^{\frac{3}{2}} - \left(\frac{c_{4}^{2}}{m^{2} - c_{4}^{2}}\right)^{\frac{3}{2}}\right\}$$

as new coefficients, and the corresponding value of

once the values of

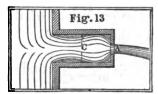

$$\frac{h_a}{h}, \text{ or } \frac{h_a}{h_b} = \frac{c_a^2}{m^2 - c_a^2} *$$

* When $\frac{h_a}{h_b} = \frac{1}{m^2 - 1} = \frac{\Lambda^2}{\sigma^2 - \Lambda^2}$ we shall have in Example II. $\frac{h_a}{h_b} = \cdot 11$ and $\left(1 + \frac{h_a}{h_b}\right)^{\frac{3}{2}} - \left(\frac{h_a}{h_b}\right)^{\frac{3}{2}} = 1\cdot 188$, Table IV., (or

It is equally applicable, therefore, to equations (41) and (42) as to equations (45) and (46). For instance, we find here at once the value of 628 $\{(1.047)^{\frac{3}{2}} \rightarrow (.047)^{\frac{3}{2}}\}$ in Example II., p. 104, equal to .666, as $\frac{h_a}{h_b} = .047$, and the next value to it for the coefficient .628, in the table, is .046, opposite to which we find .666, the new coefficient sought. The sectional area of the channel in this case, as appears from the first column, must be about three times that of the weir or notch.

Table V. is calculated from coefficients, c_4 , in still water, which vary from 550 to 1. Those from 606 to 650, and the mean value 628 are most suited for application in practice. When the channel is equal to the orifice, the supply must equal the discharge, and for open channels, with the mean coefficient 628, we find, accordingly, from the table, the new coefficient 1.002 for weirs; or 1 very nearly as it should be. We also find, in the same case, viz. when

a = c, and $c_4 = .628$, that for short tubes, Fig. 13, the resulting new coefficient becomes .807. This, as we shall afterwards see, agrees

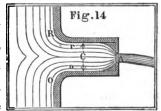

very closely with the experimental results. When the coefficients in still water are less than .628, or more correctly .62725, the orifice, according to our

Table V. for the coefficient 1.) Hence in this case $.628 \times 1.133 = .712$ the new coefficient suited to the velocity of approach. Here of course $h_a = \frac{v_a^2}{2 g c_a^2}$ (see Note p. 99).

formula, cannot equal the channel unless other resistances take place—as from friction in tubes longer than one and a half or two diameters, or in wide crested weirs; and for greater coefficients the junction of the short tube with the vessel must be

rounded, Fig. 14, on one or more sides; and in weirs or notches the approaches must slope from the crest and ends to the bottom and sides, and the overfall be sudden. The

converging form of the approaches must, however, increase the velocity of approach; and therefore v_a is greater than $\frac{A}{C} \times v_o$ when c is measured between r o and R o, Fig. 14, to find the discharge, or new coefficient of an orifice placed at r o.

As the coefficients in Table V. are suited for orifices at the end of short cylindrical or prismatic tubes at right angles to the sides or bottom of a cistern, a correction is required when the junction is rounded off as at B o r o, Fig. 14. When the channel is equal to the orifice, the new coefficient in equation (45) becomes

$$c_{\rm d} \left\{ 1 + \frac{c_{\rm d}^2}{1 - c_{\rm d}^2} \right\}^{\frac{1}{2}} = c_{\rm d} \times \left\{ \frac{1}{1 - c_{\rm d}^2} \right\}^{\frac{1}{2}}$$

The velocity in the short tube Fig. 14 is to that in the short tube Fig. 13 as 1 to $c_4 \left\{ \frac{1}{1-c_4^2} \right\}^{\frac{1}{4}}$ nearly, or for the mean value $c_4 = .628$, as 1 to .807. Now, as $\frac{c}{A}$ is assumed equal to $\frac{v_0}{v_A}$ in the cylindrical or pris-

matic tube, Fig. 13, $\frac{.807 \text{ c}}{A} = \frac{v_o}{v}$ in the tube Fig. 14 with the rounded junction, for v_a becomes $\frac{v_a}{-807}$; hence, in order to find the discharge from orifices at the end of the short tube, Fig. 14, we have only to multiply the numbers representing the ratio $\frac{C}{A}$ in the first column, Table V., by :807, or more generally by $c_d \left\{ \frac{1}{1-c^2} \right\}^{\frac{1}{2}}$, and find the coefficient opposite to the product. Thus if $c_4 = .628$, we find, when $\frac{0}{A} = 1$, $c_4 \left\{ \frac{1}{1 - c_1^2} \right\}^{\frac{1}{2}}$ = 807 in the table. If, again, we suppose $\frac{G}{A} = 3$, then $3 \times .807 = 2.421$, the value of $\frac{v_0}{v}$ for the tube Fig. 14, and opposite this value of $\frac{C}{A}$, taken in column 1. we shall find 651 for the new coefficient. cylindrical or prismatic tube, Fig. 13, the new coefficient would be only :642. When the head h is however equal to $\frac{v_{\mu}^2}{2 \sigma c_{\mu}^2}$ the results must be modified accordingly (see Note p. 99).*

$$c_{\rm d} = \frac{\cdot 618}{\left(1 - \cdot 618 \times \frac{{\rm A}^2}{{\rm c}^2}\right)^{\frac{1}{2}}}.$$

When $\frac{\Lambda}{c} = 0$, $c_d = 1$; and when $\frac{\Lambda}{c} = 1$, $c_d = .618$; as it should be very nearly for an orifice in a *thin* plate, to which only, and to Λ , in the short tube, Fig. 14, the formula is suited (see Section X).

^{*} Professor Rankine gives the value of the coefficient of discharge, or contraction, for varying values of A and c at a diaphragm in a pipe by the formula

PRACTICAL FORMULÆ FOR THE DISCHARGE OVER WEIRS,

In order to reduce the preceding formulæ for weirs and notches to some of the forms in common use, with definite combined numerical coefficients, by substituting 8.025 for $\sqrt{2g}$, equation (39) becomes for feet measures

(A.) $p_a = 5.35 c_d l \{(h_b + h_a)^{\frac{3}{2}} - h_a^{\frac{1}{2}}\},$ and for inch measures, as $\sqrt{2g} = 27.8$, the discharge, taken also in cubic feet, becomes

(B.)
$$D_a = .01072 \ c_4 \ l \ \{(h_b - h_a)^{\frac{3}{2}} - h_a^{\frac{3}{2}}\}$$

When the length l is taken in feet and the depth in inches, we shall have

(C.)
$$D_a = 1287 c_d l \{(h_b - h_a)^{\frac{3}{2}} - h_a^{\frac{3}{2}}\}$$

The three last equations being for seconds of time, we shall get, when the time is taken in minutes for feet measures, the discharge in cubic feet

(D.)
$$D_a = 321 c_d l \{(h_b + h_a)^{\frac{3}{2}} - h_a^{\frac{3}{2}}\};$$
 for inch measures

(E.)
$$D_a = .6433 \ c_d \ l \ \{(h_b + h_a)^{\frac{3}{2}} - h_a^{\frac{3}{2}}\};$$
 and for lengths (l) in feet and depths in inches

(F.)
$$D_a = 7.72 c_d l \{(h_b + h_a)^{\frac{3}{2}} - h_a^{\frac{3}{2}}\}.$$

The latter equation, when the coefficient of discharge, c_4 , is taken at .614 becomes

(G.)
$$\begin{cases} D_a = 4.74 \ l \ \{(h_b + h_a)^{\frac{3}{2}} - h_a^{\frac{3}{2}}\}, \text{ and} \\ D = 4.74 \ l \ h^{\frac{3}{2}}, \text{ when the velocity of approach vanishes.} \end{cases}$$

For a coefficient of .617

(H.)
$$\begin{cases} D_{a} = 4.76 \ l \ \{(h_{b} + h_{a}^{4})^{\frac{3}{2}} - h_{a}^{\frac{3}{2}}\} \end{cases} \text{ and} \\ D = 4.76 \ l \ h^{\frac{3}{2}} \text{ when the velocity of approach vanishes.}$$

For a coefficient of .623

(I.)
$$\begin{cases} D_a = 4.81 \ l \ \{(h_b + h_a)^{\frac{3}{2}} - h_a^{\frac{3}{2}}\} \end{cases} \text{ and } \\ D = 4.81 \ l \ h^{\frac{3}{2}} \text{ with no perceptible approach.} \end{cases}$$

For a coefficient of .628

(K.)
$$\begin{cases} D_a = 4.85 \ l \ \{(h_b + h_a)^{\frac{3}{2}} - h_a^{\frac{3}{2}}\} \end{cases} \text{ and} \\ D = 4.85 \ l \ h^{\frac{3}{2}} \text{ with no perceptible approach.} \end{cases}$$

For a coefficient of .648

(L.)
$$\begin{cases} D_a = 5 \ l \ \{(h_b + h_a)^{\frac{3}{2}} - h_a^{\frac{3}{2}}\} \end{cases}$$
 and
$$D = 5 \ l \ h^{\frac{3}{2}}$$
 with no perceptible approach.

For a coefficient of $\frac{2}{3}$ or $\cdot 667$

(M.)
$$\begin{cases} D_{a} = 5.14 \ l \ \{(h_{b} + h_{a})^{\frac{3}{2}} - h_{a}^{\frac{3}{2}}\} \end{cases} \text{ and } \\ D = 5.14 \ l \ h^{\frac{3}{2}} \text{ with no perceptible approach.} \end{cases}$$

For a coefficient of .712

(N.)
$$\begin{cases} D_a = 5.5 \ l \ \{(h_b + h_a)^{\frac{3}{2}} - h_a^{\frac{3}{2}}\} \end{cases} \text{ and } \\ D = 5.5 \ l \ h^{\frac{3}{2}} \text{ with no perceptible approach.} \end{cases}$$

And finally for a coefficient of .81

(O.)
$$\begin{cases} D_a = 6.3 \ l\{(h_b + h_a)^{\frac{3}{2}} - h^{\frac{3}{2}}\} \text{ and} \\ D = 6.3 \ l \ h^{\frac{3}{2}} \text{ when the velocity of approach} \\ \text{vanishes.} \end{cases}$$

The theoretical value of h_{\bullet} in each of the foregoing equations is in terms of the velocity of approach v_{\bullet}

$$h_{\bullet} = \frac{v_{\bullet}^2}{2 g'},$$

in which 2 g must be taken equal to 64.403 for heads in feet, and equal to 772.84 for heads in inches. But it is evident that in order to produce the velocity per second v, passing through the notch with a nearly still-water basin above it, that h_a must be increased from its theoretical value $\frac{v_a^2}{2g}$ to $\frac{v_a^2}{c_a^2 2g}$, in which expression c_a is the coefficient of discharge due to the particular notch, or weir, and its attendant circumstances; whence we must take

(P.)
$$h_a = \frac{v_a^2}{c_a^2 2 g} = \frac{\text{Theoretical head}}{c_a^2}$$
.

Now, unquestionably, the most general coefficient both for notches and submerged orifices, in thin plates, for gauging, whether triangular, rectangular, or circular, is 617, when the orifice or notch is small compared with the approaching channel; whence for measures in feet

$$h_a = .0408 \ v_a^2$$
, and $v_a = 4.95 \sqrt{h_a}$.

For measures in inches,

$$h_a = .0034 \ v_a^2$$
, and $v_a = 17.2 \ \sqrt{h_a}$.

And for measures in which v_a is expressed in feet per second, and h_a in inches

$$h_a = 49 v_a^2$$
, and $v_a = 1.43 \sqrt{h_a}$.

By substituting these values of h_a , found in terms of the approaching velocity, according to the standards used in the equations from (A) to (F) inclusive, and also in equation (H), we shall be enabled to find the proper discharge from a notch in a thin plate. The values of h_a , equation (P), can be found at once in inches from the observed values of v_a , to be also taken in inches, for coefficients varying from 584 to 974, by means of Table II. Thus, with a coefficient of 617, we shall find, for an approaching velocity of 36 inches per second, that h_a becomes $4\frac{3}{8} = 4\cdot4$ inches nearly, while for a coefficient of •666, it is only $3\frac{3}{4} =$

3.8 inches; and for a coefficient of 1, the theoretical head is but $1\frac{3}{4} = 1.7$ inches nearly.

From the very nature of the case the approaching velocity must continue nearly unimpaired through the notch with but a very slight reduction arising from the viscidity of the water when it enters the aperture, and separates from the lateral fluid. But in order to give this unimpaired velocity by means of an extra head h_a , it is evident that h_a must be increased above the theoretical value by the amount due to the coefficient of discharge; or, as before stated, h_a must be increased from $\frac{v_a^2}{2g}$ to $\frac{v_a^2}{c_d^2 2g}$. This value of h_a is, perhaps, something too large, owing to the reduction of v_a at the moment it enters the notch and is acted upon by the overfall, drawing it away, as it were, from the lateral water above the crest.

The numerical results of the respective formulæ from (A) to (0), inclusive, can be obtained by modifying the form as in equation (42) into

$$(Q.) \begin{cases} D_{a} = D \times \left\{ \left(1 + \frac{h_{a}}{\overline{h}_{b}} \right)^{\frac{3}{2}} - \left(\frac{h_{a}}{\overline{h}_{b}} \right)^{\frac{3}{2}} \right\} \text{ or,} \\ D_{a} = C_{d} \times \frac{2}{3} l h_{b} \sqrt{2g} h_{b} \times \left\{ \left(1 + \frac{h_{a}}{\overline{h}_{b}} \right)^{\frac{3}{2}} - \left(\frac{h_{a}}{\overline{h}_{b}} \right)^{\frac{3}{2}} \right\} \end{cases}$$

in which D is the discharge found, when there is no velocity of approach, by the common form D = $5.35 \times c_a l h^{\frac{3}{3}}$, for which separate values are given in equations from (H) to (o) inclusive; and numerical values in Table VI.; and $\left\{\left(1+\frac{h^a}{\overline{h}_b}\right)^{\frac{3}{2}}-\left(\frac{h_a}{\overline{h}_b}\right)^{\frac{3}{2}}\right\}$ a multiplier suited to the velocity of approach, the values of which can be found from Table IV. Suppose, for

example, D = 158.1 cubic feet per minute, $h_b = 10$ inches, and $h_a = 4$ inches, which is that due to an approaching velocity of 3 feet per second with a coefficient of .648; then the multiplier becomes $(1+4)^{\frac{3}{2}}-4^{\frac{3}{2}}=1.4035$, Table IV. Hence the discharge due to an approaching velocity of 3 feet is $158 \cdot 1 \times 1.4035 = 221.9$ cubic feet, or an increase of about 40 per cent. Also, if the common formula were used, it is plain that the coefficient .648 should be increased to $.648 \times 1.4035$, or to .909 nearly, which approximates within 10 per cent. of the theoretical value. Nothing can show more clearly the necessity for varying the coefficients when the ordinary formulæ are used, even for a notch in a thin plate: for other notches the coefficients, even for still water above the crest, vary considerably.

The form of the equation used by D'Aubuisson and several other writers is

(R.)
$$D_a = c l \sqrt{h_b^3 + c v_a^2 h_b^2}$$

in which c and c are numerical coefficients, and v_a the velocity of approach. This form is incorrect in principle, although the values of c and c can be so taken as to give resulting values for d_a approximately correct. For feet measures, and time in seconds, Professor Downing makes, after D'Aubuisson, p. 37 of his translation,

$$D_a = c_d \times 5.35 \ l \sqrt{h_b^3 + .03494 \ v_a^2 \ h_b^2}.$$

Doctor Robinson* gives for like measures and time, values varying from

$$D_a = 3.55 l \sqrt{h_b^2 + .1395 v_a^2 h_b^2}$$
, to
 $D_a = 3.2 l \sqrt{h_b^3 + .1395 v_a^2 h_b^2}$.

^{*} Proceedings Royal Irish Academy, vol. iv. p. 212. ·1895 v_a^2 is nine times the theoretical head, and too much.

Mr. Taylor finds (for the Government Referees, see Report on the Main Drainage of the Metropolis, 13th July, 1858, p. 32) the discharge in cubic feet per minute, when the depth is taken in inches, and the length in feet to be,

$$D_A = 5.5 i \sqrt{h_b^3 + .8 v_A^2 h_b^2}$$
;

and the Messrs. Hawksley, Bidder, and Bazalgette assume, (p. 33 ibid.) for like measures,

$$D_a = 5 l \sqrt{h_b^3 + 1875 v_a^2 h_b^2}$$

which they consider is in "excess." The following table, copied and extended from the report just referred to, shows the results of the last two formulæ, and of our equations (L) and (N), in which the depth, h_b , must be taken equal to 10 inches, and the length, l_b , equal to 1 foot.

Equation (L) when the head, h _a , due to the velocity of approach is increased for the coefficient of velocity .648	158·1	160	167	177	190	205	222
Equation (n) when the head, h _a , due to the velocity of approach is taken at only its theoretical value.	178-9	175-1	178-8	183-5	190-1	198·8	207-5
Equation (n) when the head due to the velocity of approach is increased for the coefficient of velocity 712	178.9	176	182	192	204	218	234
$D_{a} = 5.5\sqrt{h_{3}^{3} + .8 v_{3}^{a} h_{3}^{b}}$	178-9	175.7	180-8	188-9	199-8	218	228

In equations (L) and (N) we can get, TABLE II., the values of the head, h_a , due to velocity of approach v_a , as follows:

 $v_a = .5$, .1, 1.5, .2, 2.5, 8.0; in feet per second. $h_a = .047$, .186, .419, .745, 1.16, 1.68; theoretical head in inches. Then

 $h_a = .111$, .447, .997, 1.77, 2.76, 4:; for a coefficient of .648. and

 $h_a = 093$, 366, 383, 147, 229, 331; for a coefficient of 712. Whence as $h_b = 10$ inches, we shall have in equation (Q),

 $\frac{h_a}{h_b} = .011$, .045, .1, .18, .28, .4; for a coefficient of .648, and

 $\frac{h_a}{h_b} = .009$, .087, .088, .15, .28, .38; for a coefficient of .712; and hence, by means of TABLE IV. $\left(1 + \frac{h_a}{h_b}\right)^{\frac{3}{2}} - \left(\frac{h_a}{h_b}\right)^{\frac{3}{2}}$ becomes of the following respective values suited to the above velocities,

1-015, 1-059, 1-122, 1-205, 1-8, 1-408; for a coefficient of 648, and

1-013, 1-049, 1-104, 1-175, 1-254, 1-344; for a coefficient of -712. These latter values multiplied in order by the initial values of the discharges, 158-1 and 173-9, in the above table, give the discharges in the third and fifth lines corresponding, due to the respective velocities of approach.

The accordance between the results in the last two lines of the table is remarkable. Table V. shows that if the coefficient be '617 when the water above the crest is still, it will be increased to '712 when the approaching channel is about 1.83 times the section of the water in the notch. If the arrises of the two-inch thick waste board be rounded, the coefficient must also be considerable, although

TABLE showing the actual discharges per foot in length over a weir gauge four jest long in a sever; and the discharges by different formula brought forward during the Metropolitan Sevage Discussion. In these formula D is the Discharge in CHRC FEET PER MINUTE, h THE HELD IN INCHES, and v. THE VELOCITY OF APPROACH FEET FER SECOND. See p. 22, Letter to the Right Hon. Lord John Manners, M.P., from the Government Referes, dated 16th Aguari, 1868.
The manner of in beaining the experimental values is not stated in the Letter. The experimental discharges give values for the coefficient of discharge, c.s. from

.695 to .737 nearly.												.	٠	.	•

uncertain; but as the equation $\mathbf{p_a} = 5.5 \sqrt{h_b^3 + .8 \, v_a^2 \, h_b^2}$ appears to have been framed by Mr. Taylor, to express special experiments made for Mr. Simpson, in which the quantities varied from 5 to 152 cubic feet per minute, and for heads on a four-foot weir varying from 1 inch to 8 inches,* we must conclude the coefficient for heads measured from still water above the crest in those experiments suited to the form of the weir used, and its attendant circumstances, is .712.

The equations (39) and those from (A) to (o) may be easily changed into forms in which only the depth h_b , the velocity of approach, and the coefficient of velocity (in this case equal to that of discharge) c_a are introduced. It is, however, only necessary here to reduce the general form (A) p. 111, for feet measures, which becomes, after substituting for h_a its value

 $\frac{v_a^2}{c_a^2 \times 2g}$, and making some reductions,

$$(\mathrm{S.}) \begin{cases} \mathrm{D_a} = 5.35 c_{\mathrm{d}} \times \left(\frac{1}{c_{\mathrm{d}}^3 \times 64 \cdot 4}\right)^{\frac{3}{2}} l \left\{ \left(c_{\mathrm{d}}^3 \times 64 \cdot 4h_{\mathrm{b}} + v_{\mathrm{a}}^3\right)^{\frac{3}{2}} - v_{\mathrm{a}}^3 \right\} \\ \mathrm{D_a} = \frac{\cdot 01034}{c_{\mathrm{d}}^3} l \left\{ \left(64.4 c_{\mathrm{d}}^3 h_{\mathrm{b}} + v_{\mathrm{a}}^3\right)^{\frac{3}{2}} - v_{\mathrm{a}}^3 \right\}; \end{cases}$$

and for time in minutes the discharge is

(T.)
$$D_a = \frac{\cdot 621}{c_a^2} l \left\{ (64 \cdot 4 c_a^2 h_b + v_a^2)^{\frac{3}{2}} - v_a^3 \right\};$$

in which v_a still continues the velocity in feet per second, as determined from observation. These for-

* Vide p. 22, Letter dated 16th August, 1858, from the Government Referees to the Right Hon. Lord John Manners, on the subject of the Metropolitan Main Drainage.

mulæ may be again reduced to many others. If we take h_b in inches (T) becomes

(U.)
$$D_a = \frac{\cdot 621}{c_a^2} l\{ (5.37 c_a^2 h_b + v_a^2)^{\frac{3}{2}} - v_a^2 \}.$$

Mr. Pole, in a letter to Mr. Simpson and Captain Galton, already referred to, gives the special value,

$$D_a = 1.06 l \{ (3 h_b + v_a^2)^{\frac{3}{2}} - v_a^3 \},$$

which corresponds very closely with the experiments made for Mr. Simpson. If we assume $c_a = .712$, which also closely corresponds with those experiments, our equation (U) becomes for them

$$D_a = 1.225 l \{(2.72 h_b + v_a^2)^{\frac{3}{2}} - v_a^8\};$$

but the amount of the discharge must always depend on the coefficient c_d , equation (U) suited to the special circumstances of the case under consideration.

The form of equation for the discharge proposed by Mr. Boyden* includes the effects of the end contractions: it is

$$D = C \{l - b n h_b\} h_b^{\frac{3}{2}}$$

in which $c = \frac{3}{3} c_a \sqrt{2gh}$, n the number of end contractions, l the length of the weir, h_b the head measured from the surface of the water above the curvature of approach, and b a coefficient due to the nature of the end contractions. The mean numerical exponent of this formula, derived by Francis from his experiments, is for feet measures, per second,

$$D = 3.33 (l - 1 n h_b) h_b^{\frac{3}{2}} \dagger$$

[•] Francis's Lowell Hydraulic Experiments, p. 74.

[†] Ibid, p. 119.

but the value of a varied from 3.303 to 3.3617. These results give corresponding values of $c_d = .617$ to 628, and when c = 3.33, $c_d = 623$. The experimental results compared with this formula have been referred to at p. 83.

Francis's Lowell experiments on a wooden dam 10 feet long, level and 3 feet wide at the crest, with a head slope of 31 to 1 in a channel 10 feet wide, give, for heads between 6 and 20 inches, a mean coefficient of .563 or .565. This for feet measures would give for the discharge per second

 $p = 3.02 h^{\frac{3}{2}}$

For greater depths, on this width of crest, the discharge would probably rise as high as $3.1 h^{\frac{3}{2}}$ or $3.3 h^{\frac{3}{2}}$. The section of the dam was the same as that erected by the Essex Company across the Merrimack River, at Lawrence, Massachusetts. See, also, table of coefficients, p. 80.

In equation (13), pp. 54 and 55, we have given a general expression for the value of p through a triangular notch. Professor Thomson, of the Queen's College, Belfast, in a paper read at the British Association at Leeds in 1858, says:-

"The ordinary rectangular notches, accurately experimented on as they have been, at great cost and with high scientific skill, in various countries, with the view of determining the necessary formulas and coefficients for their application in practice, are for many purposes suitable and convenient. They are, however, but ill adapted for the measurement of very variable quantities of water, such as commonly occur to the engineer to be gauged in rivers and streams.

If the rectangular notch is to be made wide enough to allow the water to pass in flood times, it must be so wide that for long periods, in moderately dry weather, the water flows so shallow over its crest, that its indications cannot be relied on. To remove, in some degree, this objection, gauges for rivers or streams are sometimes formed, in the best engineering practice, with a small rectangular notch cut down below the general level of the crest of a large rectangular notch. If now, instead of one depression being made for dry weather, we use a crest wide enough for use in floods, we conceive of a large number of depressions extending so as to give the crest the appearance of a set of steps of stairs, and if we conceive the number of such steps to become infinitely great, we are led at once to the conception of the triangular instead of the rectangular notch. The principle of the triangular notch being thus arrived at, it becomes evident there is no necessity for having one side of the notch vertical, and the other slanting; but that, as may in many cases prove more convenient, both sides may be made slanting, and their slopes may be alike. It is then to be observed, that by the use of the triangular notch, with proper formulas and coefficients derivable by due union of theory and experiments, quantities of running water from the smallest to the largest may be accurately gauged by their flow through the same notch. The reason of this is obvious, from considering that in the triangular notch, when the quantity flowing is very small, the flow is confined to a small space admitting of accurate measurement; and that

the space for the flow of water increases as the quantity to be measured increases, but still continues such as to admit of accurate measurement.

"Further, the ordinary rectangular notch, when applied for the gauging of rivers, is subject to a serious objection from the difficulty or impossibility of properly taking into account the influence of the bottom of the river on the flow of the water to the notch. If it were practicable to dam up the river so deep that the water would flow through the notch as if coming from a reservoir of still water, the difficulty would not arise. This, however, can seldom be done in practice, and although the bottom of the river may be so far below the crest as to produce but little effect on the flow of the water when the quantity flowing is small, yet when the quantity becomes great, the velocity of approach comes to have a very material influence on the flow of the water, but an influence which is usually difficult, if not impracticable to ascertain with satisfactory accuracy. In the notches now proposed of a triangular form, the influence of the bottom may be rendered definite, and such as to affect alike (or at least by some law that may be readily determined by experiment) the flow of the water when very small, or when very great, in the same notch. The method by which I propose that this may be effected consists in carrying out a floor, starting exactly from the vertex of the notch, and extending both up-stream and latterally, so as to form a bottom to the channel of approach, which will both be smooth and will serve as the lower bounding surface of a passage of approach unchanging in form while increasing in magnitude, at the places at least which are adjacent to the vertex of the notch. The floor may be either perfectly level, or may consist of two planes, whose intersection would start from the vertex of the notch, and would pass up-stream perpendicularly to the direction of the weir board; the two planes slanting upwards from their intersection more gently than the sides of the notch. The level floor, although theoretically not quite so perfect as the floor of two planes, would probably for most practical purposes prove the more convenient arrangement.

"With reference to the use of the floor it may be said, in short, that by a due arrangement of the notch and the floor a discharge orifice and channel of approach may be produced, of which (the upper surface of the water being considered as the top of the channel and orifice) the form will be unchanged or but little changed, with variations of the quantity flowing; very much less certainly than is the case with rectangular notches.

"Whatever may be the result in this respect, the main object must be to obtain, for a moderate number of triangular notches of different forms, and both with and without floors at the passage of approach, the necessary coefficients for the various forms of notches and approaches selected, and for various depths in any one of them, so as to allow of water being gauged for practical purposes, when in future convenient, by means of similarly formed notches and approaches. The util-

ity of the proposed system of gauging it is to be particularly observed, will not depend upon a perfectly close agreement of the theory described with the experiments, because a table of experimental coefficients for various depths, or an empirical formula slightly modified from the theoretical one, will serve all purposes.

"To one evident simplification in the proposed system of gauging, as compared with that by rectangular notches, I would here advert, namely, that in the proposed system the quantity flowing comes to be a function of only one variable—namely, the measured head of water—while in the rectangular notches it is a function of at least two variables, namely, the head of water, and the horizontal width of the notch; and is commonly also a function of a third variable very difficult to be taken into account, namely, the depth from the crest of the notch down to the bottom of the channel of approach, which depth must vary in its influence with all the varying ratios between it and the other two quantities of which the flow is a function.

"The proposed system of gauging also gives facilities for taking another element into account which often arises in practice—namely, the influence of back water on the flow of the water in the gauge, when, as frequently occurs in rivers, it is found impracticable to dam the river up sufficiently to give it a clear overfall free from the back or tail water. For any given ratio of the height of the tail water above the vertex of the notch to the height of head water above the vertex of the notch, I would an-

ticipate that the quantities flowing would still be approximately at least, proportional to the power of the head, as before; and a set of coefficients would have to be determined experimentally for different ratios of the height of the head water to the height of the tail water above the vertex of the notch.

"I have got some preliminary experiments made on a right-angled notch in a vertical plane surface, the sides of the notch making angles of 45° with the horizon, and the flow being from a deep and wide pool of quiet water, and the water thus approaching the notch uninfluenced by any floor or bottom. The principal set of experiments as yet made were on quantities of water varying from about 2 to 10 cubic feet per minute; and the depths or heads of the water varied from 2 inches to 4 inches in the right-angled notch. From these experiments I derive the formula

 $Q = 0.317 \text{ H}^{\frac{5}{2}},$

where Q is the quantity of water in cubic feet per minute, and H the head as measured vertically in inches from the still water level of the pool down to the vertex of the notch. This formula is submitted at present temporarily as being accurate enough for use for ordinary practical purposes for the measurement of water by notches similar to the one experimented on, and for quantities of water limited to nearly the same range as those in the experiments; but as being, of course, subject to amendment by more perfect experiments extending through a wider range of quantities of water."

In the first edition of this book we gave the general form of the equation for the discharge through

triangular notches, and also showed the general application of the coefficients 617 to 628 for all forms of orifices and notches in thin plates. 617, as shown in note p. 55, gives a result identical with the practical results of Professor Thomson's experiments. The great advantage of the triangular notch for gauging is, that the sections for all depths flowing over are similar triangles, and therefore the coefficient probably remains constant, or nearly so, not only for one but for all species of triangles, when the depth at the open is not very little indeed in proportion to the width flowing over at the surface.

The disadvantage of the proposed triangular form of depression, if permanent in a dam, would be that the angular point should be at a lower level than the top of a horizontal crest to maintain the same level, above, of the water during floods; and therefore the power of the water and head would be reduced at the period when most required for mill-power or navigation purposes; that is, during dry weather. For drainage purposes the winter level or that during floods, must evidently be kept down, unless when the banks are steep, and along rapids; but these remarks do not apply to dams erected across millraces or streams where the banks are, generally, considerably above floods. These remarks refer to occasions for permanent gauging to find the relations of evaporation, absorption, and discharge in given catchment areas. In notch gauging to determine the useful effect of water engines, rectangular forms in thin plates have the coefficients already well determined, and the calculations are easy.

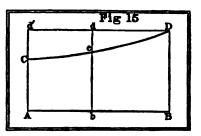

DIFFERENT EFFECTS OF CENTRAL AND MEAN VELOCITIES.

There is, however, another element to be taken into consideration, and which we shall have to refer to more particularly hereafter; it is this, that the central velocity, directly facing the orifice, is also the maximum velocity in the tube, and not the mean velocity. The ratio of these velocities is 1: 835 nearly; hence, in the example, p. 110, where $\frac{C}{A} = 3$, we get $3 \times .835 = 2.505$ for the value of $\frac{c}{A}$ in column 1, TABLE V., opposite to which we shall find 649, the coefficient for an orifice of one-third of the section of the tube when cylindrical or prismatic, Fig. 13; and $3 \times .835 \times .807 = 2.02$ nearly, opposite to which we shall get 661 for the coefficient when the orifice is at the end of the short tube, Fig. 14, with a rounded junction. We have, therefore, $\frac{C}{A} \times .835$ equal to the new value of $\frac{C}{A}$ for finding the discharge from orifices at the end of cylindrical or prismatic tubes, and $\frac{C}{A} \times .835 \times .807$ $=\frac{c}{A}\times \cdot 67$ nearly for the new value of $\frac{c}{A}$ when finding the discharge from orifices at the end of a short tube with a rounded junction.

The ratio of a mean velocity in the tube to that facing the orifice cannot be less than 835 to 1, and varies up to 1 to 1; the first ratio obtaining when the orifice is pretty small compared with the sec-

tion of the tube, and the other when they are

equal. If we suppose the curve D C, whose abscissæ (A b) represent the ratio of the orifice to the section of the tube, and whose ordinates (b c) repre-

sent the ratio of the mean velocity in the tube to that facing the orifice, to be a parabola, we shall find the following values:—

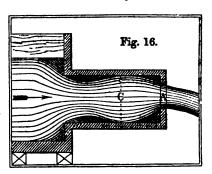

Ratio of the orifice to the channel, or values of	Values of	Ratio of the mean velocity of approach in a tube or channel to that directly opposite the erifice, or values of b c
$\frac{A}{C} = \frac{A}{A} \frac{b}{B}$	d c.

These values of bc are to be multiplied by the corresponding ratio $\frac{C}{A}$ in order to find a new value, opposite to which will be found, in the table, the coefficient for orifices at the ends of short prismatic

or cylindrical tubes; and this new value again multiplied by .807, or more generally by $c_4 \left\{ \frac{1}{1-c_2^2} \right\}^{\frac{1}{2}}$, will

give another new value of $\frac{C}{A}$, opposite to which, in the table, will be found the coefficient for orifices at the ends of short tubes with rounded junctions.

EXAMPLE III. What shall be the discharge from an orifice A, Fig. 16, 2 feet long by 1 foot deep, when the value of $\frac{C}{A}$ is 3, and the depth of the centre of A 1 foot 6 inches

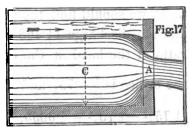

below the surface? We have $D_t = 2 \times 1 \times \frac{117'945}{13}$ (Table II.) = $2 \times 9.829 \times 19.658$ cubic feet per second for the theoretical discharge. From the table on last page the coefficient for the mean velocity, facing the orifice, is about .86; hence $\frac{C}{A} \times .86 = 3 \times .86 = 2.58$. If we take the coefficient from Table I., we shall find it (opposite to 2, the ratio of the length of the orifice to its depth) to be .617; and, for this coefficient, opposite to 2.58, in Table V., or the next number to it, we find the required coefficient .636; hence the discharge is .636 \times 19.658 = 12.502 cubic feet per second. If we assume the coefficient in still water to be .628, then we shall obtain the new co-

* See p. 106, with reference to the modifications of equations (45) and (46) into (45a) and (46a) suited to $h_a = \frac{v_a^2}{2 g c_a^2}$.

efficient .647, and the discharge would be .647 \times 19.658 = 12.719 cubic feet. If the junction of the tube with the cistern be rounded, as shown by the dotted lines, we have to multiply 2.58 by .807, which gives 2.08 for the new value of $\frac{C}{A}$, opposite which we shall find, in Table V., when the first coefficient is .628, the new coefficient .659; and the discharge in this case would be .659 \times 19.658 = 12.955 cubic feet per second.

It is not necessary to take out the coefficient of mean velocity facing the orifice to more than two places of decimals. For gauge notches in thin plates placed in

streams and millraces, Fig. 17, the mean coefficient '628, for still water, may be assumed; thence the new coefficient suited to the ratio $\frac{C}{A}$ may be found, as in the first portion of Example III. We shall leave the working out of the results when h_a is taken equal to $\frac{v_a^2}{2 \, q \, c_a^2}$ to the student.

Example IV. What shall be the discharge through the aperture A, equal 2 feet by 1 foot, when the channel is to the orifice as 3.375 to 1, and the depth of the centre is 1.25 foot below the surface, taken at about 3 feet above the orifice? Here the coefficient of the approaching velocity is .85 nearly, whence the new value of $\frac{0}{4}$ is $3.375 \times .85 = 2.87$; and as $c_4 = .628$,

we shall get from TABLE V. the new coefficient '644. Hence

 $D = 2 \times 1 \times \frac{107.669}{12} \times .644 \text{ (Table II.)} = 2 \times 8.972 \times .644$

= $17.944 \times .644 = 11.556$ cubic feet per second. Weisbach finds the discharge, by an empirical formula, to be 11.31 cubic feet. If the coefficient be sought in Table I., we shall find it 617 nearly, from which, in TABLE V., we shall find the new coefficient to be $\cdot 632$: hence $17.944 \times \cdot 632 = 11.341$ cubic feet per second. If the coefficient 6225 were used, we should find the new coefficient equals .638, and the discharge 11:468 cubic feet. Or thus: The ratio of the head at the upper edge to the depth of the orifice is $\frac{9}{12}$ = .75, and from Table IV. we find $(1.75)^{\frac{3}{2}} - (.75)^{\frac{3}{2}} = 1.6655$. Assuming the coefficient to be .644, we find from TABLE VI. the discharge per minute over a weir 12 inches deep and 1 foot long to be $\frac{208.650 + 206.119}{2} = 206.884$ cubic feet nearly; and as the length of the orifice is 2 feet, we have $\frac{2 \times 206 \cdot 884 \times 1 \cdot 6655}{2 \times 206 \cdot 884 \times 1 \cdot 6655} = 11.482$ cubic feet per second, which is the correct theoretical discharge for the coefficient ·644, and less than the approximate result, 11·556 cubic feet above found, by only a very small dif-The velocity of approach in this example must be derived from the surface inclination of the stream. The working out of this example and the increase of the discharge when $h_a = \frac{v_a^2}{2 \ \sigma \ c_a^2}$ will afford practice to the student.

For notches or Poncelet weirs the approaching velocity is a maximum at or near the surface. If the central velocity at the surface facing the notch be 1, the mean velocity from side to side will be 914. We may therefore assume the variation of the central to the mean velocity to be from 1 to 914; and hence the ratio of the mean velocity at the surface of the channel to that facing the notch or weir cannot be less than 914 to 1, and varies up to 1 to 1; the first ratio obtaining when the notch or weir occupies a very small portion of the side or width of the channel, and the other when the weir extends for the whole width. Following the same mode of calculation as at p. 129, Fig. 15, we shall find as follows:—

.0 .086 .914 .1 .085 .915 .2 .083 .917 .3 .078 .922 .4 .072 .928 .5 .064 .936 .6 .055 .945 .7 .044 .956 .8 .031 .969 .9 .016 .984 1.00 .000 1.000	Ratio of the width of the notch to the width of the channel.	Values of de, Fig. 15.	Values of b c, Fig. 15.

These values of b c are to be used as before in order to find the value of $\frac{C}{A}$, opposite to which in the

tables, and under the heading for weirs, will be found the new coefficient.

Example V. The length of a weir is 10 feet; the width of the approaching channel is 20 feet; the head, measured about 6 feet above the weir, is 9 inches; and the depth of the channel 3 feet: what is the discharge? Assuming the circumstances of the overfall to be such that the coefficient of discharge for heads, measured from still water in a deep weir basin or reservoir, will be .617, we shall find from TABLE VI. the discharge to be $128.642 \times 10 = 1286.42$ cubic feet per minute; but from the smallness of the channel the water approaches the weir with some velocity, and $\frac{C}{A} = \frac{20 \times 8}{10 \times \frac{3}{4}} = 8$. We have also the width of the channel equal to twice the width of the weir, and hence (small table, p. 133,) $8 \times .936 = 7.488$ for the new value of $\frac{C}{A}$. From Table V. we now find the new coefficient $\frac{.622 + .624}{2} = .623$, and hence the discharge is $\frac{1286\cdot42 \times \cdot 623}{617} = 1298\cdot93$ cubic feet per minute. Or thus: As the theoretical discharge, TABLE VI., is 2084.96 cubic feet, we get $2084.96 \times .623 = 1298.93$, the same as before. In this example, however, the mean velocity approaching the overfall bears to the mean velocity in the channel a greater ratio than 1: 936, as, though the head is pretty large in proportion to the depth of the channel, the ratio of the sections $\frac{A}{C} = \frac{1}{8}$ is small. We shall therefore be more correct by finding the multiplier from the small table,

p. 129. By doing so the new value of $\frac{\text{C}}{\text{A}}$ is $8 \times .838$ = 6.704. From this and the coefficient .617 we shall find, as before from Table V., the new coefficient to be .627; hence we get $2084.96 \times .627 = 1307.27$ cubic feet per minute for the discharge.

The foregoing solution takes for granted that the velocity of approach is subject to contraction before arriving at the overfall or in passing through it; now, as this reduces the mean velocity of approach from 1 to .784, Table V., when the coefficient for heads in still water is 617, we have to multiply the value of $\frac{C}{A} = 6.704$, last found, by 784, and we get $6.704 \times .784 = 5.26$ for the value $\frac{c}{A}$ due to this correction, from which we find the corresponding coefficient in Table V. to be 629, and hence the corrected discharge is $2084.96 \times .629 = 1311.44$ cubic It is to be borne in mind that the value of $\frac{C}{A}$ in TABLE V. is simply an approximate value for the ratio of the velocity in the channel facing the orifice to the velocity in the orifice itself; and the corrections applied in the foregoing examples were for the purpose of finding this ratio of velocity more correctly than the simple expression $\frac{C}{A}$ gives it. The following auxiliary table will enable us to find the correction. and thence the new coefficient, with facility. if the channel be five times the size of the orifice, and a loss in the approaching velocity takes place equal to that in a short cylindrical tube, we get

AUXILIARY TABLE, TO BE USED WITH TABLE V. FOR MORE NEARLY FINDING THE COEFFICIENT OF DISCHARGE NEARLY SUITED TO EQUATIONS $(45\,a)$ and $(46\,a)$.

 $5 \times .842 = 4.210$ for the new value of $\frac{C}{A}$, opposite to which, in Table V., will be found the coefficient sought. If the coefficient for still water be .606, we shall find it to be .612 for orifices and .623 for weirs. But when the water approaches without loss of velocity, we find from the auxiliary table .64 for the multiplier instead of .842, and consequently the new value of $\frac{C}{A}$ becomes $5 \times .64 = 3.2$, from which we shall find .617 to be the new coefficient for orifices and .636 for weirs. The auxiliary table is calculated by multiplying the numbers in the second column (see third column, table, p. 129) by the value of $c_a \times \left\{\frac{1}{1-c_a^3}\right\}^2$, which will be found from Table V., for the different values of c_a in the table, viz.

·639, ·628, ·617, ·606, ·595, ·584, and ·573, to be ·831, ·807, ·784, ·762, ·740, ·719, and ·699 respectively, as given in the top and bottom lines of figures.

When $\frac{c_d^2}{m^2-c_s^2}$ in equations (45) and (46) is equal to $\frac{1}{m^2-1}$ in equations (45a) and (46a), then $c_d=1$, and $c_4 \left\{ 1 + \frac{c_4^2}{m^2 - c_2^2} \right\}^{\frac{1}{2}}$ in equation (45) is equal to $\left\{1 + \frac{1}{m^2 - 1}\right\}^{\frac{1}{2}}$ in equation (45a); and c_a $\left\{(1 + \frac{1}{m^2 - 1})^{\frac{1}{2}}\right\}$ $\frac{c_4^2}{m^2-c_1^2}$ $\frac{3}{2}$ $-\left(\frac{c_4^2}{m^2-c_1^2}\right)^{\frac{3}{2}}$ in equation (46) is equal to $\left\{\left(1+\frac{1}{m^2-1}\right)^{\frac{3}{2}}-\left(\frac{1}{m^2-1}\right)^{\frac{3}{2}}\right\}$ in equation (46a); and therefore the coefficient found from TABLE V. for $c_d = 1$ will give the multiplier for c_d , outside the brackets, in (45a) and (46a), to find the new coeffi-Thus in the last example m = 5, and hence Table V. for $c_d = 1$, we find $\left\{1 + \frac{1}{m^2 - 1}\right\}^{\frac{1}{2}} = 1.021$ and $\left\{ \left(1 + \frac{1}{m^2 - 1}\right)^{\frac{3}{2}} - \left(\frac{1}{m^2 - 1}\right)^{\frac{3}{2}} \right\} = 1.055.$ $1.021 \times .606 = .619$ nearly; and $1.055 \times .606 = .639$ nearly, the new coefficients found from the other method being .617 and .636, the difference by both methods being of no great practical importance.

It is necessary to observe, that in equations (45), (46), (45a), and (46a), the head due to the velocity of supply or approach, h_a , must be extra to the head h, and no part of it, and that—as is indicated by the equations—m can never be so small as unity. These equations are not, therefore, strictly applicable to orifices in the short tubes, Fig. 15 and Fig. 16, al-

though they can be made practically so within definite limits. The initial value of $c_{\rm d}$ itself varies considerably with the position and form of the orifice; for a mean value of $\cdot 707$ it changes according to the rela-

tion of c and A into $\frac{.707}{(1-.5\frac{A^2}{C^2})^{\frac{1}{2}}}$, and for a value of

'618 for an orifice, central in a thin plate, Professor Rankine's formula, p. 110, is applicable.

In weirs at right angles to channels with parallel sides, the sectional area can never equal that of

the channel unless it be measured at or above the point A, where the sinking of the overfall commences; and unless also the bed c D and surface A B have the same inclination. In all open channels, as mill-races, streams, rivers, the supply is derived from the surface inclination of AB, and this inclination regulates itself to the discharging power of the overfall. When the overfall and channel have the same width, and it is considerable, we have, as shall appear hereafter, $91 \sqrt{h s}$ for the mean velocity in the channel, where h is the depth in feet and s the rate of inclination of the surface AB. We have also

 $\frac{2}{8}$ $\sqrt{2gh}$ for the theoretical velocity of discharge at the overfall, of equal depth with the channel, and, when both velocities are equal,

$$\frac{2}{8}\sqrt{2gh} = 5.35\sqrt{h} = 91\sqrt{hs};$$

from which we find

$$s=\frac{1}{289}=.00346$$
,

the inclination of B A when the supply is equal to the theoretical discharge at the overfall. If the coefficient at the overfall were $\cdot 628$, or, which is nearly the same thing, if a large and deep weir basin intervene between the weir and channel, Fig. 19, A α

would be level, the velocity of approach would be destroyed, and we should have

$$5.35 \times .628 \sqrt{h} = 3.36 \sqrt{h} = 91 \sqrt{hs}$$
; and thence the inclination of AB

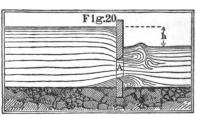

$$s = \frac{1}{784} = .00136$$

very nearly. When we come to discuss the surface inclination of rivers, we shall see that the conditions here assumed and the resulting surface inclinations would involve a considerable loss of head. If the quantity discharged under both circumstances be the same, and h be the depth in the first case, Fig. 18, we shall then have the head in the latter case, Fig. 19, equal $\left(\frac{5.35}{3.36}\right)^{\frac{5}{3}}h = 1.36h$ very nearly, from which and the surface inclination the extent of the backwater may be found with sufficient accuracy. When, in Fig. 19, the inclination of h be exceeds h the head at h must exceed the depth of the river above h. We must refer to pages further on, Section h, for some remarks on the backwater curve.

SECTION V.

SUBMERGED ORIFICES AND WEIRS.—CONTRACTED RIVER CHANNELS.

The available pressure at any point in the depth of the orifice A, Fig. 20, is equal to the difference of the pressures on each side.

This difference is equal to the pressure due to the height h, between the water surfaces on each side of the orifice; in this case, the velocity is

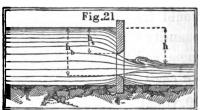

$$(47.) v = c_{\rm d} \sqrt{2gh};$$

and the discharge

$$(48.) D = l d c_d \sqrt{2gh};$$

in which, as before, l is the length, and d the depth of the rectangular orifice A.

When the orifice is partly submerged, as in Fig. 21, we may put $h_b = h = d_2$ for the submerged depth,

and $h = h_1 = d_1$, the remaining portion of the depth; whence $d_1 + d_2 = d$ is the entire depth. The discharge through the submerged depth d_2 is $c_4 l d_2 \times \sqrt{2 g h}$, and the discharge through the upper portion d_1 is

$$\frac{2}{3} c_{\rm d} l \sqrt{2g} \{h^{\frac{3}{2}} - h_{\rm t}^{\frac{3}{2}}\};$$

whence the whole discharge—assuming the coefficient of discharge c_4 is the same for the upper and lower depths—is

(49.)
$$D = c_d l \sqrt{2g} \left\{ d_2 \sqrt{h} + \frac{2}{3} (h^{\frac{3}{2}} - h_1^{\frac{3}{2}}) \right\}.$$

We may, however, equation (31), assume that

$$\frac{2}{3}c_{\rm d} \, l \, \sqrt{2g} \, (h^{\frac{3}{2}} - h^{\frac{3}{2}}) = c_{\rm d} \, d_1 \, l \, \sqrt{2g(h - \frac{d_1}{2})}$$

very nearly, and hence

(50.)
$$D = c_a l d_a \sqrt{2gh} + c_a l d_1 \sqrt{2g(h_t - \frac{d_1}{2})}$$

As $h_t + \frac{d_1}{2} = h - \frac{d_1}{2}$ this equation may be changed into

(51.)
$$D = c_d l d_2 \sqrt{2gh} + c_d l d_1 \sqrt{2g(h_1 + \frac{d_1}{2})}$$

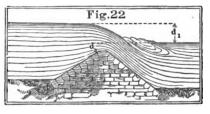

In either of these forms the values of

$$c_d \sqrt{2gh}$$
, $c_d \sqrt{2g(h-\frac{d_1}{2})}$, and $c_d \sqrt{2g(h_t+\frac{d_1}{2})}$

can be had from TABLE II., and the value of the discharge D thence easily found.

When the water approaches the orifice with a determinate velocity, the height h_a due to that velocity can be found from Table II., and the discharge is then found by substituting $h + h_a$ and $h_t + h_a$ for h and h_t in the above equations.

In the submerged weir, Fig. 22, h becomes equal to d_1 , and $h_1 = 0$; the discharge, equation (49), then becomes

(52.)
$$\begin{cases} D = c_4 l d_2 \sqrt{2g d_1} + \frac{2}{3} c_4 l d_1 \sqrt{2g d_1}, \text{ or} \\ D = c_4 l \sqrt{2g d_1} \left\{ d_2 + \frac{2}{3} d_1 \right\}. \end{cases}$$

When the water approaches with a velocity due to the height h_a , then h becomes $h + h_a$, $h_t = h_a$, and equation (49) becomes

(53.)
$$D = c_4 l \sqrt{2g} \left\{ d_2 \sqrt{d_1 + h_a} + \frac{2}{3} (d_1 + h_a)^{\frac{3}{2}} - h_a^{\frac{3}{2}} \right\}$$

In the improvement of the navigation of rivers, it is sometimes necessary to construct weirs so as to raise the upper waters by a given depth, d_1 . The discharge D is in such cases previously known, or easily determined, and from the values of d_1 and D we can easily determine, equation (52), the value of

(54.)
$$d_2 = \frac{D}{c_d l \sqrt{2 g d_1}} - \frac{2}{3} d_1;$$

or, by taking the velocity of approach into account,

(55.)
$$d_2 = \frac{D}{c_4 l \sqrt{2g(d_1 + h_a)}} - \frac{2}{3} \frac{(d_1 + h_a)^{\frac{3}{2}} - h_a^{\frac{3}{2}}}{\sqrt{d_1 + h_a}}.$$

This value of d_2 must be the depth of the top of the weir below the original surface of the water, in order that this surface should be raised by a given depth, d_1 . When h_2 is small compared with d_2 , we may take

$$\frac{2}{3}(d_1 + h_a) = \frac{2}{8} \times \frac{(d_1 + h_a)^{\frac{3}{2}} - (h_a)^{\frac{3}{2}}}{\sqrt{d_1 + h_a}} \text{ in equation (55)}.$$

EXAMPLE VI. A river whose width at the surface is 70 feet, whose hydraulic mean depth is 4.4 feet, and whose cross sectional area is 325 feet, has a surface inclination of 1 foot per mile; to what depth below, or height above the surface must a weir at right angles

To find horizontal distance to which cases of water from a main creat with shoot in the course of a given fall below that evert, take 1.33 x mean proportional between that fur - height of wein event to surface of shill water in pand.

to the channel be raised, so that the depth of water immediately above it shall be increased by $3\frac{1}{2}$ feet?

When the hydraulic mean depth is 4.4 feet, and the fall per mile 1 foot, we find from TABLE VIII. that the mean velocity of the river is 29.98 or 30 inches very nearly per second. The discharge is, therefore, $325 \times 2\frac{1}{2} = 812.5$ cubic feet per second, or 48750 cubic feet per minute. Hence, $\frac{48750}{70}$ = 696.4 cubic feet, must pass over each foot in length of the weir per minute. Assuming the coefficient $c_d = .628$ in the first instance, we find from Table VI. the head passing over a weir corresponding to this discharge to be 27.4 inches; but as the head is to be increased by 3½ feet, or 42 inches, it is clear that the weir must be perfect; that is, have a clear overfall, and rise 42 - 27.4 = 14.6 inches over the original water surface. In order that the weir may be submerged, or imperfect, the head could not be increased by more than 27.4 inches. Let us, therefore, assume in the example, that the increase shall be only 18 instead of 42 inches; the weir then becomes submerged, and we have, from equation (54),

$$d_2 = \frac{696 \cdot 4}{628 \sqrt{18'' \times 2q}} - \frac{2}{3} \times 18'' \text{ (as } l = 1 \text{ foot)}.$$

The value of the first part of this expression is found from Table VI. or Table II. equal to

$$\frac{696.4}{\frac{12}{18} \times \frac{8}{2} \times 370.341} = \frac{696.4}{370.341} = 1.88 \text{ feet} = 22.56 \text{ in.};$$

hence $22.56 - \frac{36}{3} = 10.56$ inches is the value of d_2 ;

that is, the submerged weir must be built within 10.56 inches of the surface to raise the head 18 inches above the former level. If, however, the velocity of approach be taken into account, we shall find this velocity equals $\frac{812.5}{430} = 2$ feet per second very nearly; and the height, or value of h_a , due to this velocity, taken from Table II., is $\frac{3}{4} = .75$ inches nearly; therefore, from equation (55),

$$d_2 = \frac{696 \cdot 4}{\cdot 628 \sqrt{2} g \times 18 \cdot 75'} - \frac{2}{3} \times \frac{(18 \cdot 75)^{\frac{3}{3}} - (\cdot 75)^{\frac{3}{3}}}{\sqrt{18 \cdot 75}}.$$

The value of
$$\frac{696.4}{\cdot 628 \sqrt{2g \times 18.75'}}$$
 = (from Table VI.)

$$\frac{696.4}{\frac{8}{2} \times \frac{12}{18.75} \times 393.75} = \frac{696.4}{378.8} = 1.84 \text{ feet} = 22.08 \text{ in.};$$

also,
$$\frac{2}{3} \times \frac{(18.75)^{\frac{3}{3}} - (.75)^{\frac{3}{3}}}{\sqrt{18.75}} = \frac{2}{3} \times 18.75 - \frac{2}{8} \times \frac{(.75)^{\frac{3}{3}}}{\sqrt{18.75}}$$

$$=12.5 - \frac{2}{8} \times \frac{.65}{4.33} = 12.5 - .1 = 12.4.$$

Hence $d_2 = 22.08 - 12.4 = 9.68$ inches, or about 1 inch less than the value previously found from equation (54). The mean coefficient of discharge was here assumed to be .628. Experiments on submerged weirs show that the value of c_d varies from .5 up to .8, but as this coefficient would reduce the value of d_2 , or the depth of the top of the weir below the surface, it is safer (where a given depth above a weir

^{*} This is found from TABLE II. more readily.

must be obtained) to use the lesser and ordinary coefficients of perfect weirs, with a clear overfall, for finding the crest levels of submerged weirs, when it is necessary to construct them. If the coefficient 8 were used in the previous calculation, we should have found

$$d_2 = \frac{.628 \times 22.08}{.8} - 12.4 = 17.33 - 12.4 = 4.93 \text{ in.,}$$

or not much more than half the previous value; but this would only increase the whole height of the weir by 9.68 - 4.93 = 4.75 inches.

As $D = \frac{2}{8}c_d l \sqrt{2g} \{(d_1 + h_a)^{\frac{3}{2}} - h_a^{\frac{3}{2}}\}$ for a perfect weir with a free overfall, it is clear that when D is greater than $\frac{2}{8}c_d l \sqrt{2g} \{(d_1 + h_a)^{\frac{3}{2}} - h_a^{\frac{3}{2}}\}$, the weir is imperfect or submerged. For backwater curve see Section X.

In the following table of coefficients from Lesbros* d_2 is measured from that point below the weir where its value is a minimum. On examining equation (52), it will be seen that the equation $D = c_d l$ $(d_1 + d_2) \sqrt{2g d_1}$ adopted by Lesbros is incorrect, and can only be safely used within the limits of his experiments.

	raines are those shown be I below the lower once, v		

The true value of the discharge is expressed by the equation $D = c_d l \left\{ \frac{2}{3} d_1 + d_2 \right\} \times \sqrt{2 g d_1}$, and the values of c_d in the above table are, therefore, too small, applied to the correct formula. When $d_1 = d_2$ the table gives $c_d = \cdot 474$. Now for weirs in which the sheet passing over is "drowned," the general value of the coefficient is about .67; this would give the coefficient for the lower portion d_2 , in the true formula, equal to .503, and a mean coefficient c_d in the correct formula (52) equal to .569 nearly. When $d_2 = 200 d_1$, the apparent limits of the experiments on the other side, then the mean value of $c_d = \cdot 496$ nearly in equation (52). These results would show that the coefficient due to the submerged depth d_2 , in the first and last experiments,

is equal to about 5 nearly, (but varies to 6 nearly in some of the middle experiments,) or thereabouts, and, therefore, equation (52) for submerged weirs, as the coefficient for the upper part d_1 is 67, would become

(52A.)
$$D = l \times \{ \cdot 445 \ d_1 + \cdot 5 \ d_2 \} \times \sqrt{2 g \ d_1};$$
 which for feet measures would become again (52B.) $D = l \times \sqrt{d_1} \times \{ 3 \cdot 56 \ d_1 + 4 \ d_2 \}$, for the discharge in cubic feet per second over a submerged weir, Fig. 22.

CONTRACTED RIVER CHANNELS.

When the banks of a river, whose bed has a uniform inclination, approach each other, and contract the width of the channel in any way, as in

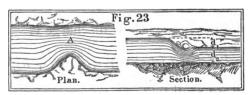

Fig. 23, the water will rise in the channel above the contracted portion A, until the increased velocity of discharge compensates for the reduced cross section. If we put, as before, d_1 for the increase of depth immediately above the contracted width, and d_2 for the previous depth of the channel, we shall find the quantity of water passing through the lower depth, d_2 , equal to $c_d l d_2 \sqrt{2 g d_1}$, in which l is the width of the contracted channel at A, and the quantity of

water overflowing through d_1 equal to $\frac{2}{8} c_4 l d_1 \sqrt{2g d_1}$;

and hence the whole discharge through A is

(56.)
$$D = c_d l \sqrt{2g d_1} \left(d_2 + \frac{2}{3} d_1 \right)$$

When our object is to find the width l of the contracted channel, so that the depth of water in the upper stretch shall be increased by a given depth d_1 , we shall find

(57.)
$$l = \frac{D}{c_4 \sqrt{2g d_1} \left(d_2 + \frac{2}{8} d_1\right)}$$

When the velocity of approach is considerable, or when the height h_{\bullet} due to it becomes a large portion of d_1 , its effect must not be neglected. In this case, as before, we find the discharge through the depth d_2 equal to $c_d l d_2 \sqrt{2g(d_1 + h_{\bullet})}$; and the discharge through the depth d_1 equal to $\frac{2}{3} c_d l \sqrt{2g} \left\{ (d_1 + h_{\bullet})^{\frac{3}{2}} \right\}$

 $-h_a^{\frac{3}{2}}$; and hence the whole discharge is

(58.)
$$D = c_4 l \sqrt{2g} \{ d_2 (d_1 + h_a)^{\frac{1}{2}} + \frac{2}{8} [(d_1 + h_a)^{\frac{3}{2}} - h_a^{\frac{3}{2}}] \};$$
 from which we shall find

(59.)
$$l = \frac{D}{c_a \sqrt{2g} \{d_2(d_1 + h_a)^{\frac{1}{2}} + \frac{2}{3} [(d_1 + h_a)^{\frac{3}{2}} - h_a^{\frac{3}{2}}]\}}$$

If the projecting spur or jetty at a be itself submerged, these formulæ must be extended; the manner of doing so, however, presents no difficulty, as it is only necessary to find the discharges of the different sections according to the preceding formulæ, and then add them together; but the resulting formula so found is too complicated to be of much practical value.

HEADS ARISING FROM PIERS AND BACKWATER ABOVE BRIDGES.

Equations (56), (57), (58), and (59), are applicable to cases of contraction of river channels caused by the construction of bridge-piers and abutments, when the width l is put for the sum of the openings between The value of the coefficient c_d will depend on the peculiar circumstances of each case; we have seen that it rises from .5 to .7 in some cases of submerged weirs, and for cases of contracted channels it rises sometimes as high as .8, particularly when they are analogous to those for the discharge through mouth-pieces and short tubes. When the heads of the piers are square to the channel, the coefficient may be taken at about .6; when the angles of the cut-waters or sterlings are obtuse, it may be taken at about .7; and when curved and acute, at ·8. With this coefficient, a head of 24 inches will give a velocity of very nearly 36 inches, or 3 feet per second; but as a certain amount of loss takes place from the velocity of the tail-water being in general less than that through the arch, also from obstructions in the passage, and from square-headed and very short piers, the coefficient may be so small in some cases as .5, which would require a head of 62 inches to obtain the same velocity. This head is to the former as 54 to 21. The selection of the proper coefficient suited to any particular case is, therefore, a matter of the first importance in determining the effect of obstructions in river channels: we shall have to recur to this subject again, but it is necessary to observe here, that the form of the approaches, the

length of the piers compared with the distance between them, or span, and the length and form of the obstruction compared with the width of the channel, must be duly considered before the coefficient suited to the particular case can be fixed upon. Indeed, the coefficients will always approximate towards those, given in the next section, for mouth-pieces, shoots, and short tubes similarly circumstanced. For some further remarks on contracted channels, see Section X.

SECTION VI.

SHORT TUBES, MOUTH-PIECES, AND APPROACHES.—ALTERATION IN THE COEFFICIENTS FROM FRICTION BY INCREASING THE LENGTH.—COEFFICIENTS OF DISCHARGE FOR SIMPLE AND COMPOUND SHORT TUBES.—SHOOTS.

The only orifices we have heretofore referred to were those in thin plates or planks, with a few incidental exceptions. It has been shown, page 48, Fig. 4, that a rounding off, next the water, of the mouthpiece increases the coefficient; and when the curving

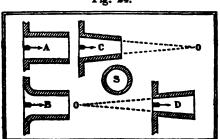

Fig. 24.

assumes the form of the vena-contracta, the coefficient increases to 986, or nearly unity. The discharge

from a short cylindrical tube A, Fig. 24, whose length is from one and a half to three times the diameter, is found to be very nearly an arithmetical mean between the theoretical discharge and the discharge through a circular orifice in a thin plate of the same diameter as the tube, or .814 nearly. If, however, the inner arris be rounded, or chamfered off in any way, the coefficient will increase until, in the tube B, Fig. 24, with a properly-rounded junction, it becomes unity very nearly. In the conical short tubes c and D the coefficients are found to vary according to some function of the converging or diverging angles o, o, and according as we take the lesser or greater diameter to calculate from. When the length of the tube exceeds twice the diameter, the friction of the water against the sides may be taken into account.

The following table, calculated by us, for a coefficient of friction '00699, due to a discharging velocity of about eighteen inches per second, see Section VIII., shows the resistance arising from friction in pipes of different lengths in relation to the diameter, and will be found of considerable practical value. It will be perceived that the calculations are made for three different orifices of entry. First, when the arrises are rounded, as in B, Fig. 24, with a coefficient of '986; secondly, when the arrises are square, as in A, with a coefficient of '815; and, thirdly, when the pipe projects into the vessel, when the coefficient of entry becomes reduced to '715. The velocity is

$$v \equiv c_a \sqrt{2 g h}$$

h being measured to the lower end of the tube.

We see from this table, that the effect of adding to the length of the pipe is greatest next the orifice of entry. The effect of a few diameters added to the length in long pipes is, practically, immaterial; but in short pipes it is considerable.

As for orifices in thin plates, so also for short tubes, the coefficients are found to vary according to the depth of the centre below the surface of the water, and to increase as the depths and diameter of the tube decrease. Poleni first remarked that the discharge through a short tube was greater than that through a simple orifice, of the same diameter, in the proportion of 133 to 100, or as '617 to '821.

CYLINDRICAL SHORT TUBES, A, FIG. 24.

The experiments of Bossût, as reduced by Prony, give the following coefficients, at the corresponding depths, for a cylindrical tube A, Fig. 24, 1 inch in diameter and 2 inches long. The depths are given in

COEFFICIENTS FOR SHORT TUBES, FROM BOSSUT.

Paris feet in the original, but the coefficients remain the same, practically, for depths in English feet.

Venturi's experiments give a coefficient 823 for a short tube A, 1½ inch in diameter and 4½ inches long, at a depth of 2 feet 8½ inches, the coefficient through an orifice in a thin plate of the same diameter and at the same depth being 622. We have calculated these coefficients from the original experiments. The measures were in Paris feet and inches, from which the calculations were directly made; and as the difference in the coefficient for small changes of depth or dimensions is immaterial or vanishes, as may be seen by the foregoing small table, and as 1 Paris inch or foot is equal to 1.0658 English inches or feet, the former measures exceed the latter by only

about 1sth. We may therefore assume that the coefficient for any orifice, at any depth, is the same, whether the dimensions be in Paris or English feet or inches. This remark will be found generally useful in the consideration of the older continental experiments, and will prevent unnecessary reductions from one standard to another where the coefficients only have to be considered.

The mean value derived from the experiments of Michelotti, at depths from 3 to 20 feet, and with short tubes A from $\frac{1}{2}$ inch to 3 inches in width, is $c_d = .814$. Buff's experiments* give the following results for a tube $\frac{3}{10}$ of an inch wide and $\frac{5}{10}$ of an inch long, nearly.

11	·855	6	·8 4 0	23	-829
21	-861	14	• 84 0	82	-826

BUFF'S COEFFICIENTS FOR SMALL SHORT TUBES.

The increase for smaller tubes and for lesser depths appears by comparing these results with the foregoing, and from the results in themselves, generally. Weisbach's experiments give a mean value for $c_4 = .815$, and for depths of from 9 to 24 inches the coefficients .843, .832, .821, .810 respectively, for tubes $\frac{4}{10}$, $\frac{8}{10}$, $\frac{12}{10}$, and $\frac{16}{10}$ of an inch wide, the length of each tube being three times the diameter. D'Aubuisson and Castel's

^{*} Annalen der Physik und Chemie von Poggendorff, 1839. Band 46, p. 243.

experiments with a tube '61 inch diameter and 1.57 inch long, give '829 for the coefficient at a depth of 10 feet. When a pipe projects into a cistern and has a sharp edge, the coefficient falls so low as '715.

We have calculated the coefficients in the two following short tables, from Rennie's experiments with glass orifices and tubes, Table 7, p. 435, Philosophical Transactions for 1831. The form of the orifices, or length of the shorter tubes is not stated, but it is probable from the result, that the arrises of the ends were in some way rounded off; it is stated they were "enlarged." Indeed, the discharges from the short tube or orifice of 1 inch diameter exceed the theoretical ones in the proportion of 1.261 to 1, and 1.346 to 1. These results could not have been derived from a simple cylindrical tube, but might have arisen from the arrises being more or less rounded at both ends, and the orifice partaking of the nature of a compound tube, which may be constructed, as we shall hereafter show, so as to increase the theoretical discharge from 1 up to 1.553. The resulting coefficients for the 4

and $\frac{3}{4}$ inch tubes, approach very closely to those obtained by other experimenters, but those for the inch tube are too high, unless the arris at the ends was also rounded. The coefficients derived from the

experiments with a cylindrical glass tube 1 foot long, as here given, are very variable; like the others they

are, however, valuable, as exhibiting the uncertainty attending "experiments of this nature," and the necessity for minutely observing and recording every circumstance which tends to alter and modify them. Indeed, for small tubes, a very slight difference in the measurement of the diameter must alter the result a good deal, particularly when it is recollected that measurements are seldom taken more closely than the sixteenth of an inch, unless in special cases. As the author, however, states, p. 433 of the work referred to, that the "diameters of the tubes at their extremities were carefully enlarged to prevent wire edges from diminishing the sections;" this circumstance alone must have modified the discharges, and would account for most of the differences.

The coefficient for rectangular short tubes differs in no way materially from those given for cylindrical ones, and may be taken on an average at 814 or 815.

SHORT TUBES WITH A ROUNDED MOUTH-PIECE, B, FIG. 24.

When the junction of a short tube with a vessel takes the form of the contracted vein, Figs. 3 and 4, page 48, the mean value of the coefficient $c_a = 956$,

and the actual discharge is found to be from 93 to 99 per cent. of the theoretical discharge. Weisbach, for a tube $1\frac{1}{2}$ inch long and $\frac{2}{10}$ inch diameter, rounded at the junction, found at 1 foot deep $c_d = .958$, at 5 feet deep $c_d = .969$, and at 10 feet deep $c_d = .975$. These experiments show an increase in the coefficients, in this particular case, for an increase of depth. Any other form of junction than that of the contracted vein, will reduce the discharge, and the coefficients will vary from .715 to .814, and to .986, according to the change in the junction from the cylindrical, projecting into the vessel, to the square and properly curved forms. The coefficients derived from Venturi's experiments will be given hereafter.

SHORT CONICAL CONVERGENT TUBES, C, FIG. 24.

The experiments of D'Aubuisson and Castel lead to the following coefficients of discharge and velocity* from a conically convergent tube c at a depth of 10

Converging angle o.	Coefficient of discharge.	Coefficient of velocity.	Converging angle o.	Coefficient of discharge.	Coefficient of velocity.

COEFFICIENTS FOR CONICAL CONVERGENT TUBES.

^{*} Traité d'Hydraulique, Paris, p. 60.

feet. We have interpolated the original angles and coefficients so as to render the table more convenient to refer to, for practical purposes, than the original. The diameter of the tube at the smaller or discharging orifice in the experiments was .61 inches, and the length of the axis 1.57 inch; that is, the length was 2.6 times the smaller diameter of the tube. coefficient became 829 for the cylindrical tube, i.e. when the angle at o was nothing. The angle of convergence o determines, from the proportions, the length of the inner and longer diameter of the tube. The coefficients of discharge increase up to .943 for an angle of 131 or 14 degrees, after which they again decrease; but the coefficients of velocity increase as the angle of convergence, o, increases from 829, when the angle is zero up to 985 for an angle of 50 degrees.

When D is the discharge and A the area of the section, we have, as before shown, $D = c_d \ A \ \sqrt{2gh}$; but as, in conically convergent or divergent tubes, the inner and outer areas (or, as they may be called, the receiving and discharging sections) vary, it is clear that, the discharge being the same, and also the theoretical velocity $\sqrt{2gh}$, the coefficient c_d must vary inversely with the sectional area A, and that $c_d \times A$ must be constant. For the coefficients tabulated, the sectional area to be used is that at the smaller or outside end of a convergent tube c, Fig. 24.

For a short tube c, whose length is .92 inch, lesser diameter 1.21 inch, and greater diameter 1.5 inch, we have found, from Venturi's experiments, that $c_4 = .607$ if the larger diameter be used in the calcu-

lation, and $c_a = 934$ when the lesser diameter is made use of, the discharge taking place under a pressure of 2 feet $8\frac{1}{4}$ inches.

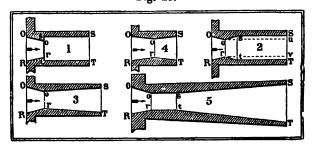

The earlier experiments of Poleni, when reduced, furnish us with the following coefficients: A tube 7.67 inches long, 2.167 inches diameter at each end, gave $c_d = .854$; the like tube with the inner or receiving orifice increased to $2\frac{3}{4}$ inches, $c_d = .903$; increased to 3.5 inches, $c_d = .898$; increased to 5 inches, $c_d = .888$; and increased to 9.83 inches, $c_d = .864$. The depth or head was 21.33 inches, the discharging orifice 2.167 inches diameter, and the length 7.67 inches, in each case.

In the conically divergent tube p, Fig. 24, the coefficient of discharge is larger than for the same tube c, convergent, when the water fills both tubes, and the smaller sections, or those at the same distances from the centres o o, are made use of in the calculations. A tube whose angle of convergence, o, is 5° nearly, with a head of from 1 to 10 feet, whose axial length is 31 inches, smaller diameter 1 inch, and larger diameter 1.3 inch, gives, when placed as at c, .921 for the coefficient; but when placed as at D, the coefficient increases to .948. In the first case the smaller area, used in both calculations, being the receiving, and in the other the discharging, orifice. The coefficient of velocity is, however, larger for the tube c than for the tube p, and the discharging jet of water has a greater amplitude in falling. effects of conically diverging tubes will, however, be better perceived from the experiments on compound short tubes.

EFFECTS OF COMPOUND ADJUTAGES AND ADMISSION OF AIR INTO SHORT TUBES.

If the tube A, Fig. 24, be pierced all round with small holes at the distance of about half its diameter from the reservoir, the discharge will be immediately reduced in the proportion of .814 to .617. Venturi found the reduction for a tube 11 inch diameter and 4½ inches long, at a depth of 2 feet 10½ inches, as 41 to 31, or as .823 to .622. As long as one hole remained open, the discharge continued at the same reduced rate; but when the last hole was stopped, the discharge again increased to the original quantity. If a small hole be pierced in a tube 4 diameters long, at the distance of 1½ or 2 diameters at farthest from the junction, the discharge will remain unaffected. This shows that the contraction in the cylindrical tube extends only a short distance from the junction, probably 11 or 11 diameter, including the whole curvature of the contraction.

The contraction at the entrance into a tube from a reservoir accounts for the coefficients for a short tube A, Fig. 24, and the short tubes, diagrams 1 and 2, Fig. 25, being each the same decimal nearly, when Fig. 25.

 $oR: or::1:\cdot 8$, or when or is not less than $oR \times \cdot 79$,

and is at the distance of nearly $\frac{OR}{2}$ from OR. The form of the junction OPR remaining as we have described it, the following coefficients will enable us to judge of the discharging powers of differently formed short mouth-pieces. They have been deduced and calculated by us, principally, from Venturi's experiments.*

These coefficients show very clearly that any caldulations from the mere head of water and size of the orifice, without taking into consideration the form of the discharging tube and its connection with the reservoir, are very uncertain; and that the discharge can only be correctly obtained when all the circumstances of the case, including the form of the discharging orifice and its approaches, have been duly considered.

When a tube similar to diagram 5, Fig. 25, has the junction o or R rounded, as in Fig. 4, page 48, the outer extremity st st, such that st = or, ss = 9 st, and the diameter st = 1.8 times the diameter st, with a short central cylindrical piece orst between, the coefficient of discharge corresponding to the diameter or = rs will increase to 1.493 or 1.555; that is, the discharge is $\frac{1.493}{.622} = 2.4$, or $\frac{1.555}{.622} = 2.5$ times as much as through an orifice (whose diameter is or) in a thin plate, and $\frac{1.565}{.822} = 1.9$ times as much as through a

^{*} See Nicholson's translation of Venturi's Experimental Inquiries, published in the Tracts on Hydraulics, London, 1886. The coefficients in the table, next page, have been all calculated for the first time by us.

short cylindrical tube A, Fig. 24, whose diameter is also or. Venturi was of opinion that this discharge continued even when the central cylindrical portion orst was of considerable length; but this was a mistake, as the maximum discharge is obtained when it is reduced so that oor R and sst shall join, as in diagram 3, Fig. 25. We see from No. 16 of the fore-

going coefficients that $\frac{1\cdot 569}{\cdot 622} = 2\cdot 52$ and $\frac{1\cdot 569}{\cdot 822} = 1\cdot 91$ are, perhaps, nearer to the maximum results obtainable by comparing the discharge from a compound tube $0 \circ 5 \tau r$, diagram 3, Fig. 25, with those through an orifice in a thin plate, and through a short cylin-

drical tube. When the form of the tube becomes curvilineal throughout, as in Fig. 26, $s \tau = 1.8 \ o \ r$ and $o s = 9 \ o \ r$,

the coefficient suited to the diameter or will be 1.57

nearly, and the discharge will be $\frac{1.57}{.622} = 2.52$ times as much as through an orifice o r in a thin plate.

The whole of the preceding coefficients have been determined from circumstances in which the coefficient for an orifice in a thin plate was 622, and for a short cylindrical tube 822 or 823. When the circumstances of head and approaches in the reservoir are such as to increase or decrease those primary coefficients, the other coefficients for compound adjutages will have to be increased or decreased proportionately.

After examining the foregoing results, it appears sufficiently clear that the utmost effect produced by

the fermation of the compound mouth piece o be nor Ri. with the exception of No. 17, is simply a restoration. of the loss effected by contraction in passing through. the orifice on in a thin plate, and that the coefficient. 2:5 applied to the contracted section at a rie simply equal to the theoretical dischurge, or the coefficient, unity, applied to the primary orifice o R; for, as orifice o R : orifice o r :: 1 : .64, very nearly, when oor a takes the form of the vena-contracta, and the coefficient of discharge for an orifice of r in a thin plate is 622, we get the theoretical discharge through the orifice or R. to the actual discharge, through an orifice o r, so is 1 to 622 \times 64, so is 1: 39808 :: 1 : 4 very nearly; and as $4 \times 2.5 = 1$, it is clear that the form of the tube gosnrs, when it produces the foregoing effect, simply restores the loss caused by contraction in the vena-contracta. Venturi's sixteenth experiment, from which we have derived the coefficients in No. 17, gives the coefficient 1.215 for the orifice o R. This indicates that a greater discharge than the theoretical, through the receiving orifice, may be obtained. It is, however, observable that Venturi, in his seventh proposition, does not rely on this result, and Eytelwein's experiments do not give a larger coefficient than 2.5 applied to the contracted orifice or, which, we have above shown, is equal to the theoretical discharge through o R.

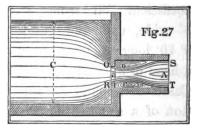

SHOOTS.

When the sides and under edge of an orifice or notch increase in thickness, so as to be converted into a shoot or small channel, open at the top, the coefficients reduce very considerably, and to some extent beyond what the increased resistance from friction, particularly for small depths, indicates. Poncelet and Lesbros* found for orifices 8" × 8" that the addition of a horizontal shoot 21 inches long reduced the coefficient from 604 to 601, with a head of about 4 feet; but for a head of 41 inches the coefficient fell from 572 to 483. For notches 8" wide, with the addition of a horizontal shoot 9' 10" long, the coefficient fell from 582 to 479 for a head of 8"; and from 622 to 340 for a head of 1". Castel also found for a notch 8 wide, with the addition of a shoot 8'long, inclined 4' 18', the mean coefficient for heads from 2" to 4\frac{1}{2}", to be 527 nearly. The effects arising from friction alone will be perceived from the short table at the beginning of this section; p. 152. Versa role // lo mundos gri //olimo sult The orifice of entry into a shoot and its position with reference to the sides and bottom modify the discharge, the head remaining constant. Lesbrost has given the coefficients suited to different positions of shoots both within and without a cistern, and from notches and submerged orifices; but, however valuable these are in some respects, they are of little practical use to the engineer. The general principles which are involved in the modification of these coeffcients have, however, been already pointed out; by us when discussing the effects of the position of the orifice, and the addition of short tubes, on the discharge. Equation (74s.), p. 189, is here applicable. * Uld and I * Traite d'Hydraulique, pp. 46 et 9420 las limitals Wide Morin's Hydranlinne, denxième édition, pp. 29 et 40.

SECTION VII.

LATERAL CONTACT OF THE WATER AND TUBE.—ATMOSPHERIC PRESSURE.—HEAD MEASURED TO THE DISCHARGING ORIFICE.—COEFFICIENT OF RESISTANCE.—FORMULA FOR THE DISCHARGE FROM A SHORT TUBE.—DIAPHRAGMS.—OBLIQUE JUNCTIONS.—FORMULA FOR THE TIME OF THE SURFACE SINKING A GIVEN DEPTH.—LOCK CHAMBERS.

The contracted vein or is about 8 times the diameter or; but it is found, notwithstanding, that water, in passing through a short tube of not less

than 11 diameter in length, fills the whole of the discharging orifice s T. This is partly effected by the outflowing column of water carrying forward and exhausting the air between it and the tube, and by the external air then pressing on the column so as to enlarge its diameter and fill the whole tube. When once the water approaches closely to the tube, or is caused to approach, it is attracted and adheres with some force to it. The water between the tube and the vena-contracta is, however, rather in a state of eddy than of forward motion, as appears from the experiments, with the tube, diagram 2, Fig. 25, giving the same discharge as the simple cylindrical tube. If the entrance be contracted by a diaphragm, as at o R, Fig. 27, the water will also generally fill the tube, if it be only sufficiently long. Short cylindrical tubes do not fill when the discharge takes place in an exhausted receiver; but even diverging tubes, p, Fig. 24, will be filled, under atmospheric pressure, when the angle of divergence, o, does not exceed 7 or 8 degrees, and the length be not very great nor very short.

When a tube is fitted to the bottom or side of a vessel, it is found that the discharge is that due to the head measured from the surface of the water to the lower or discharging extremity of the tube. It must, however, be sufficiently long, and not too long, to get filled throughout. Guiglielmini first referred this effect to atmospheric pressure, but the first simple explanation is that given by Dr. Mathew Young, in the Transactions of the Royal Irish Academy, vol. vii., p. 56. Venturi, also, in his fourth, proposition, gives a demonstration.

The values of the coefficients for short cylindrical tubes, which we have given p. 162, have been derived from experiment. Coefficients which agree pretty closely with them, and which are derived from the coefficients for the discharge through an orifice in a thin plate, may, however, be calculated as follows: Let c be the area of the approaching section, Fig. 27, A the area of the discharging short tube, and a the area of the orifice on which admits the water from the vessel into the tube: also put, as before, h for the head measured from the surface of the water to the centre of the tube, and diaphragm on; v for the actual velocity of discharge at s τ ; v, for the velocity of approach in the section c towards the diaphragm o R; and c_a for the coefficient of contraction in passing from or to or; then we have $c \times v_* = A \times v_*$ the contracted section $or = c_0 \times a$, and consequently the velocity at the contracted section is equal to

Now a theoretical head equal to $\frac{v^3-v_a^3}{2 g} = \frac{v^3 \left(1-\frac{A^3}{C^2}\right)}{2 g}$ is necessary to change the velocity v_a into v by the action of gravity; but as the water at the contracted section ar, moving with a velocity $\frac{Av}{ac}$, strikes against the water between it and TS, moving, from the nature of the case, with a slower velocity; a certain loss of effect takes place from the impact. If this be supposed, sudden, then writers on mechanics have shown that a loss of head, equal to that due to the difference of the velocities, $\frac{A v}{a c_n} - v$, before and after the impact must take place. This loss of head is therefore equal to $\frac{\sqrt{\frac{\mathbf{A}}{a\,\mathbf{c}_o}}\mathbf{1}\mathbf{1}\mathbf{v}^{\mathbf{a}_i}}{2\,g}, \text{ mult fit } \mathbf{v} \text{ else in }$ whence we must have the whole head, to sent our constant of $\frac{\lambda^2}{(60.5)} = \frac{\lambda^2}{(60.5)} = \frac{\lambda^2}{(60.5$ from which we find for the velocity from a short tube: 2 g h would be the velocity of discharge were there no resistances, or loss sustained, it * Vide Sir Robert Kane's translation of Ruhlman's book on Horizontal Water Wheels, p. 49m are will be vigoriev will

were a coefficient of velocity. When the diameter of the diaphragm on becomes equal to the diameter ar of the tube, A = q, and as the coefficient of velocity becomes equal to the coefficient of discharge when there is no contraction, we get in such case this coefficient. which we shall also call cof, expressed by the formula of explanation $\begin{cases} \frac{1}{2} & \frac{1}{2} & \frac{1}{2} & \frac{1}{2} \end{cases}$ (62.) $\begin{pmatrix} c & c & f \\ -c & c & f \\ -c & f \end{pmatrix} = \begin{cases} \frac{A^2}{C^2} + \begin{pmatrix} 1 \\ -c & f \end{pmatrix} \end{cases}$ (7) and the analysis of the contraction of the contraction f and f are the contraction of the contraction f and f are the contraction of the contraction f and f are the contraction of the contraction f and f are the contraction of the contraction f and f are the contraction of and when the approaching section c is very large

compared with the area A,

If $c_0 = 64$, we shall find from the last equation bof = 872; if c = 601, o of = 1889; if d = 617. e by = 847; and if e ± 621; e by = 856; 17hese results are in excess of those derived from experimenti with cylindrical short tubes, perfectly square at the ends and of uniform bore. As some loss, however, takes place in the eddy between or and the tube, and from the friction at the sides, not taken into account in the above calculation, they will account for the differences of not more than from 4 to

When the disphragm is placed in a tube of uniform bore, then of A, and we shall get and have a found or make

and the loss of head, in passing the disphragm, becomes
$$h = \left(\frac{A}{a c_0} - 1\right)^2 \times \frac{v^2 + v^2 + 1}{2g}$$
This evident from the equations that $\frac{A}{a}$ and $\frac{A}{a}$ depend mutually expected as $\frac{A}{a}$.

It is evident from the equations that $\frac{1}{a}$ and s_a depend mutually on each other, and that they cannot be assumed arbitrarily. See equations (66), (67), (124), and (125), with the corresponding semerts. 6 per cent. between the calculation and experiment. If c_o be assumed for calculation equal 590, then $c \circ f = .821$; and as this result agrees very closely with the experimental one, c_o should be taken of this value in using the foregoing formulæ, from (60) to (63), for practical purposes. The thickness of the diaphragm itself and the relation of that thickness to the diameter, as well as the form of the orifice a, are necessary elements in the consideration of this question.

COEFFICIENT OF RESISTANCE.—LOSS OF MECHANICAL POWER IN THE PASSAGE OF WATER THROUGH THIN PLATES AND PRISMATIC TUBES.

The coefficients of contraction, velocity, and discharge have been already defined. The coefficient of resistance is the ratio of the head due to the resistance, to the theoretical head due to the actual or final velocity. If v be this latter velocity, the theoretical head due to it is $\frac{v^2}{2g}$; and if c_r be the coefficient of resistance, then the head due to the resistance itself is, from our definition, $c_r \times \frac{v^2}{2g}$. Now if c_r be the coefficient of velocity, the theoretical velocity of discharge must be $\frac{v}{c_r}$, and the head due to it is equal $\frac{v^2}{c_r^2 \times 2g}$; but as the theoretical head due to v is $\frac{v^2}{2g}$, we shall have

$$\frac{v^{a}}{c_{v}^{a} \times 2g} - \frac{v^{a}}{2g} = \left(\frac{1}{c_{v}^{a}} - 1\right) \frac{v^{a}}{2g}$$

for the head due to the resistance; and, therefore, from our definition, the coefficient of resistance

(64.)
$$c_r = \frac{1}{c^3} - 1;$$

from which we shall find the coefficient of velocity

(65.)
$$c_r = \left\{\frac{1}{c_r + 1}\right\}^{\frac{1}{2}}$$

These equations enable us to calculate the coefficient of resistance from the coefficient of velocity, and vice versa. If $c_r = 1$, $c_r = 0$, as it should be. The following short table, calculated from equation (65), will be of use. In short tubes, the coefficient of velocity c_r is equal to the coefficient of discharge c_a .

Coefficient Coefficient Coefficient Coefficient Coefficient Coefficient of velocity. of resistance of velocity. of resistance of velocity. of resistance. .990 .020 ·910 ·208 ·830 ·452 .970 .063 ·890 .263 ·820 ·488 .950 ·109 .870 .320 ·814 .508 .880 .156 850 .383 ·810 .525

COEFFICIENTS OF VELOCITY AND RESISTANCE.

The coefficient of velocity for an orifice in a thin plate, or for a mouth-piece, Fig. 4, is .974; while that for a short prismatic tube, A, Fig. 24, is .814 nearly. The coefficient of resistance in the former case is .054, and in the latter .508; there is, therefore, 9.4 times as great a loss of mechanical power in the passage through short prismatic tubes, as through orifices in thin plates or tubes with a rounded junction, as in Fig. 4, the quantities of water discharged and the discharging velocities being the same.

If the quantities discharged and the heads be the same in both cases, then we shall have

$$\frac{v_i^2}{2 g \times \cdot 814^2} = \frac{v_o^2}{2 g \times \cdot 974^2}$$
 equal the head;

^{*} See the tables of resistances, discharge, and contraction, pp. 174 and 176.

that is, $\frac{v_i^3}{.663 \times 2g} = \frac{v_o^3}{.949 \times 2g}$, or .949 $v_i^3 = .663 v_o^3$; whence we get of =: 698 v and v = 1 431 v for the relation of the discharging velocities, v_o , from an orifice, and, v, from a short tube. The height due to the resistance is therefore, $(\frac{1}{814^2} + 1)\frac{v_1^2}{2g}$ for short prismatic tubes, and $(\frac{1}{974^2}, \frac{1}{1})$ $\frac{1.431}{2g}$ for orifices in thin plates. These are to each other as 508 ito $.054 \times 1.431$, or as .5.08 to .773, that is to say, the loss of mechanical power arising from the resistance in passing through short tubes is 6:57 times as great as when the water passes through thin plates or mouth-pieces, as in Fig. 4; and the discharging mechanical power in plates, is to that in tubes as 1.431 to 1, or as 1: 698, the heads and quantities discharged being the same included to maintage off The whole loss of mechanical nower in the passage is 5.4 per cent. for the plates, and about 51 per cent. for short tubes. ... If the loss compared with the whole head, be sought, we get, when viis, the discharging velocity, 814 for the theoretical velocity due to the bend in short tubes, and its square 11814 = 1663 is as the whole head; therefore, the whole head is to the head due to the discharging velocity as .663 to 2, or as 1 to 663; and as 508; is the coefficient of trasistance* for the discharging velocity, 508 × 663 = 337 is the coefficient of resistance due to the مين هاي او ريي او بين کووه دين the leaves to solder the one

^{*} Table, p. 171. 071 bus 431 .qq

whole head; this is equal to a loss of 34 per centurestly, or about one-third. In like manner, we find 9743 × 054 = 10512 for the coefficient when the discharge takes place through thin plates, or 5½ per cent. of the whole head.

DIAPERAGES! TO THE CONTROL OF DEEL

When a diaphragm, to R, Fig. 27, is placed at the entrance of a short tube, we have shown, page 168,

that a loss of head equal $\frac{\left(\frac{A}{a \cdot c_o}-1\right) v^2}{2 \cdot g}$ takes place when v is the discharging velocity, whence the coefficient of resistance is equal to $\left(\frac{A}{a \cdot c_o}-1\right)$, according to our definition. The coefficient of contraction c_o , as we have before shown, page 170, should be taken equal to 590 in the application of formula (63); and, as it must also be taken equal to about 621 when the area of the tube A is very large compared with the area a of the orifice or in the diaphragm, we may assume that when $\frac{a}{A}$ is equal to

0, 1, 2, 8, 4, 5, 6, 7, 8, 9, and 1 successively, the coefficient c_o must be taken equal to 621, 618, 615, 612, 609, 606, 608, 600, 597, 598, and 590, in the same order. As the approaching section σ

* For the sudden alteration in the velocity passing through a diaphragm, we must reject the hypothesis of D'Aubuisson, Traité d'Hydraulique, p. 238, and adopt that of Navier, taking the loss of head to correspond to the square of the difference and not to the difference of the squares of the velocities in and after passing the orifice. The coefficient of contraction must, however, be varied to suit the ratio of the channels, as it is in this and the following pages.

may be considered exceedingly large, the value of the coefficient of discharge or velocity, as the tube or strip is supposed full, in equation (61), becomes

(66.)
$$c_d = \left\{ \frac{1}{1 + \left(\frac{A}{a c_0} - 1\right)^3} \right\}^{\frac{1}{3}},$$

and the coefficient of resistance

(67.)
$$c_{\rm r} = \left(\frac{\Lambda}{a c_{\rm o}} - 1\right)^{2};$$

from which equations and the above values of c_o , corresponding to $\frac{a}{\Lambda}$, we have calculated the following values of the coefficients of discharge and resistance through the tube or st. Fig. 27.

COEFFICIENTS OF CONTRACTION, DISCHARGE, AND RESISTANCE FOR DIAPHRAGMS.

0.5	·606	-899	5∙8	•••	••		•••

In this table c_c is the coefficient of contraction, c_d the coefficient of discharge, suited to the larger section of the pipe A, at s T; and c_r the coefficient of resistance. The discharge is found from equation (61), as c is here very large compared with A, to be

(67A.)
$$D = A \sqrt{2gh} \left\{ \frac{1}{1 + \left(\frac{A}{ac_c} - 1\right)^2} \right\}^{\frac{1}{2}}$$

$$= A \sqrt{2gh} \left\{ \frac{1}{1 + c_r} \right\}^{\frac{1}{2}} = c_d A \sqrt{2gh}.$$

The coefficient of resistance c_r is here equal $\left(\frac{A}{a c_c} - 1\right)^3$, and the coefficient of discharge $c_d = \frac{1}{(1 + c_r)^2}$.

The tube must be so placed, that the water, after passing the diaphragm, shall fill it; for instance, between two cisterns, when the height h must be measured between the water surfaces, or when the tube is sufficiently long to be filled; in this case, however, the height must be determined from the discharging velocity, as a portion of the head is required to overcome the friction, which we shall have immediately to refer to more particularly.

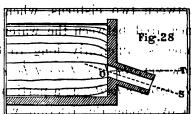

The table shows that the head due to the resistance is 5.3 times that due to the discharging velocity, when the area of the diaphragm is half the area of the tube; that is, the whole head required is 6.3 times that due to the velocity, and that the coefficient of discharge is reduced to .399. In order to find the coefficients suited to the smaller area of the orifice in the diaphragm o'R, when it is to be used in calculations of the discharge, we have only to divide the numbers corresponding to $\frac{a}{A}$ into those of c_4 , opposite to them in the table. Thus, when $\frac{a}{A} = .8$, we have the coefficient of discharge suited to the area a,

^{*} For the loss sustained by contraction in the bore of a pipe by a diaphragm, see equations (128), (124), and (125). The actual value of c_0 in equation (67A) depends on the thickness of the diaphragm as well as on the relation of a and A. The form of the orifice a also affects the value of c_0 .

equal $\frac{675}{8}$ = 1844, and so of other values of the ratio $\frac{a}{A}$. The coefficients in the table, page 174, are for the larger orifice A in the formula $D = A c_A \sqrt{2gh}$.

of When a tube is at

tached obliquely, as in
Fig. 28, we have found
that if the number of
degrees in the angle
To s, formed by the

direction of the tube o's, with the perpendicular o'r, be represented by ϕ , then 814-0016 ϕ will give the coefficient of discharge corresponding to the obliquely attached short tube in the Figure. This formula is, however, empirical, but it is simple, and agrees pretty closely with experimental results. As the coefficient of resistance is equal $\frac{1}{\sigma_{\star}^2} = 1$, equation (64), we have

here $c_r = \frac{1}{(.814 - .0016 \,\phi)^2} - 1$; from these equations we have calculated the following table for heads measured to the middle of the outside orifice:—

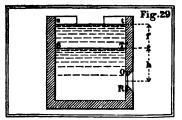

COEFFICIENTS OF DISCHARGE AND RESISTANCE FOR OBLIQUE JUNCTIONS.

The coefficient of resistance for a tube at right angles to the side, is to the like coefficient when it makes an angle of 45 degrees as .508 to .816, or as 1 to 1.6 nearly; and the loss of head is greater in the same proportion. If the short tube be more than three or four diameters in length, friction will have to be taken into account. The head h is measured to the outside orifice.

FORMULA FOR FINDING THE TIME THE SURFACE OF WATER
IN A CISTERN TAKES TO SINK A GIVEN DEPTH.—DISCHARGE FROM ONE VESSEL OR CHAMBER INTO ANOTHER.
—LOCK CHAMBERS.

In experiments for finding the value of the coefficients of discharge, one of the best methods is to observe the time the water discharged from the orifice

takes to sink the surface in a prismatic cistern a given depth; the ratio of the observed to the theoretical time will then give the coefficient sought. A formula for finding the theoretical time is, therefore, of much practical value. In Fig. 29, the time of falling from s t to s T, in seconds, is

(68.)
$$t = \frac{A}{4.0125 a} \{ (h+f)^{i} - h^{i} \},$$

in which a is the area of the orifice o R, and A the area of the prismatic vessel at st or st; this formula is for measures in feet. For measures in inches, we have

(69.)
$$t = \frac{\Lambda}{13.9a} \{ (h+f)^{\frac{1}{2}} - h^{\frac{1}{2}} \}.$$

EXAMPLE VII. A cylindrical vessel 5.74 inches in diameter has an orifice ·2 inch in diameter at a depth

of 16 inches below the surface, measured to the centre; it is found that the water sinks 4 inches in 51 seconds; what is the coefficient of discharge?

The theoretical time t is found from equation (69), equal

$$\frac{5 \cdot 74^2 \times \cdot 7854}{13 \cdot 9 \times \cdot 2^2 \times \cdot 7854} \{16^4 - 12^4\} = \frac{32 \cdot 9476}{\cdot 556} \{4 - 3 \cdot 4641\}$$

$$= \frac{17 \cdot 6566}{\cdot 556} \times \cdot 5359 = 31 \cdot 8 \text{ seconds}; \text{ hence, } \frac{31 \cdot 8}{51} = \cdot 624$$
is the coefficient sought. When the orifice o R and the horizontal section of the vessel are similar figures,
$$\frac{A}{a} \text{ is equal } \frac{S}{OR^2}; \text{ and therefore, for circular cisterns}$$
and orifices, it is unnecessary to introduce the multiplier $\cdot 7854$.

We have given above, formulæ for the time water in a prismatic vessel takes to fall a given depth, when dis-

Fig. 29a.

charged from an orifice at the side or bottom. The time the surface s T, diagram 1, Fig. 29a, takes to rise to s t, when supplied through an orifice or tube o R, from an upper large chamber or canal, whose surface

s' t' remains always at the same level, is
$$\frac{2 \text{ A} f^{\frac{1}{4}}}{c_{\text{d}} \alpha \sqrt{2g}}$$
,*

^{*} The time of rising from s to s is exactly double the time it would take, if the pressure f remained uniform, to fill the same depth below R.

and we thence get the time of rising from R to S for measures in feet

(69A.)
$$t = \frac{A}{4.015c_{*}a} \{h_{!}^{1} - f_{!}^{1}\},$$

and for measures in inches

(69B.)
$$t = \frac{A}{13 \cdot 9c_4 a} \{h_1^4 - f^4\},$$

in which A is the area of the horizontal section at $s\tau$; a the sectional area of the communicating channel or orifice oR; c_d the coefficient of discharge suited to it, and h_1 and f, as shown in the diagram.

In order to find the time of filling the lower vessel to the level s τ , supposing it at first empty, we have the contents of the portion below o κ equal to λh_2 , and the time of filling it equal to

(69c.)
$$\frac{Ah_2}{8.025 c_4 a h_1}$$
;

then the time of filling up to any level s T, for measures in feet, is equal to the sum of (A) and (C); that is,

(69D.)
$$\mathbf{T} = \frac{\mathbf{A}h_{1}^{1}}{8\cdot025\,c_{4}a} \left\{ 2 + \frac{h_{2}}{h_{1}} - \frac{2f^{1}}{h_{1}^{1}} \right\} = \frac{\mathbf{A}\left(2h_{1} + h_{2} - 2f^{1}h_{1}^{1}\right)}{8\cdot025\,c_{4}a\,h_{1}^{1}},$$

and for measures in inches

(69E.)
$$\mathbf{T} = \frac{\mathbf{A}h_1^1}{27 \cdot 8c_a a} \left\{ 2 + \frac{h_2}{h_1} - \frac{2f^4}{h_1^4} \right\} = \frac{\mathbf{A}(2h_1 + h_2 - 2f^4h_1^4)}{27 \cdot 8c_a ah_1^4}.$$

When sr coincides with st

(69f.)
$$T = \frac{\Lambda (2h_1 + h_2)}{8.025 c_4 a h_1^2},$$

for measures in feet, and

(69g.)
$$T = \frac{A(2h_1 + h_2)}{27.8 c_4 a h_1^2},$$

for measures in inches. These equations are exactly suited to the case of a closed lock-chamber filled from an adjacent canal.

When the upper level s' T' is also variable, as in Diagram 2, the time which the water in both vessels takes to come to the same uniform level s' t' s t. is

(69H.)
$$t = \frac{2 \operatorname{AC}(h_1 + f_1 - h)^{\frac{1}{4}}}{c_d a (\operatorname{A} + \operatorname{C}) \sqrt{2g}} = \frac{2 \operatorname{AC}(f + f_1)^{\frac{1}{4}}}{c_d a (\operatorname{A} + \operatorname{C}) \sqrt{2g}};$$

in which $h_1 + f_1 - h = f + f_1$ is the difference of levels at the beginning of the flow; c the horizontal section of the upper chamber; and the other quantities as in Diagram 1. As $cf_1 = Af$, we find

$$f+f_1=\frac{C+A}{A}f_1=\frac{C+A}{C}f.$$

Now, in order to find the time of falling a given depth d below the first level s' t', we have the head above s' t' s t equal to $f_1 - d$ in the upper vessel, and the depth below it in the lower vessel equal to $\frac{C(f_1-d)}{A}$; whence the difference of levels in the two vessels at the and of the fall d is

vessels at the end of the fall d, is

$$f_1-d+\frac{c(f_1-d)}{A}=\frac{A+c}{A}(f_1-d).$$

The time of falling through d is, therefore, from equation (69 H),

(69I.)
$$t = \frac{2 \text{ ac} (f + f_1)^{\frac{1}{6}}}{c_4 a (\text{A} + \text{C}) \sqrt{2g}} - \frac{2 \text{ ac} \left\{ \left(\frac{\text{C} + \text{A}}{\text{A}}\right) (f_1 - d) \right\}^{\frac{1}{6}}}{c_4 a (\text{A} + \text{C}) \sqrt{2g}}$$
$$= \frac{2 \text{ ac}}{c_4 a (\text{A} + \text{C}) \sqrt{2g}} \left\{ (f + f_1)^{\frac{1}{6}} - \left(\frac{(\text{A} + \text{C}) (f_1 - d)}{\text{A}}\right)^{\frac{1}{6}} \right\},$$

in which $\sqrt{2g} = 8.025$ for measures in feet, and equal 27.8 for measures in inches. The whole time of filling to a level the lower empty vessel, is found by adding the time of filling the portion below R, determined in a manner similar to equations (68) and (69) to be

(69K.)
$$\frac{2c}{c_d a \sqrt{2g}} \left\{ (h_1 + f_1)^{\frac{1}{2}} - \left(h_1 + f_1 - \frac{h_2 A}{C}\right)^{\frac{1}{2}} \right\}$$

to the time of filling above R, given in equation (H), when h is taken equal to zero. Equations (H), (I), and (K) are applicable to the case of the upper and lower chambers of a double lock, after making the necessary change in the diagrams.

The above equations require further extensions when water flows into the upper vessel while also flowing from it into the lower; such extensions are, however, of little practical value, and we therefore omit them. For sluices in flood-gates with square arrises, c_4 may be taken at about 545, but with rounded arrises, the coefficient will rise much higher. See Sections III. and VI.

SECTION VIII.

FLOW OF WATER IN UNIFORM CHANNELS.—MEAN VELOCITY.—
MEAN RADII AND HYDRAULIC MEAN DEPTHS.—BORDER.
—TRAIN.—HYDRAULIC INCLINATION.—EFFECTS OF FRICTION.—FORMULÆ FOR CALCULATING THE MEAN VELOCITY.
—APPLICATION OF THE FORMULÆ AND TABLES TO THE SOLUTIONS OF THREE USEFUL PROBLEMS.

In rivers the velocity is a maximum along the central line of the surface, or, more correctly, over the deepest part of the channel; and it decreases thence to the sides and bottom: but when backwater arises from any obstruction, either a submerged weir, Fig. 22, or a contracted channel, Fig. 23, the velocity in the channel approaching the obstruction is a maximum at the depth of the backwater below the surface, and it decreases thence to the surface, sides, and bottom. When water flows in a pipe of any length, the velocity at the centre is greatest, and it decreases thence to the sides or circumference of the pipe. If the pipe be supposed divided into two portions in the direction of its length, the lower portion or channel will be analogous to a small river or stream, in which the velocity is greatest at the central line of the surface, and the upper portion will be simply the lower reversed. A pipe flowing full may, therefore, be looked upon as a double stream, and we shall soon see that the formulæ for the discharge from each kind are all but identical, though a pipe may discharge full at all inclinations, while the inclinations in rivers or streams, having uniform motion, never exceed a few feet per mile.

MEAN VELOCITY.

It is found, by experiment, that the mean velocity is nearly independent of the depth or width of the channel, the central or maximum velocity being the same. From a number of experiments, Du Buât derived empirical formulæ equivalent to

$$v = \frac{v_b + v}{2} = v - v^b + \frac{1}{2}, v_b = (v^b - 1)^2, \text{ and } v = (v_b^b + 1)^2;$$

in these equations v is the mean velocity, v the maximum surface velocity, and v, the velocity at the sides, or bottom, expressed in French inches. Tables calculated from these formulæ do not give correct results for measures in English inches, though they are those generally adopted. Disregarding the difference in the measures, which are as 1 to 1.0678, it will be found that, in the generality of channels, the mean velocity is not an arithmetical mean between the velocity at the central surface line and that at the bottom, though nearly so between the mean bottom and mean surface velocities. Dr. Young,* modifying Du Buât's formula, assumes for English inches that $v + v^{\dagger} = v$, and hence $v = v + \frac{1}{2} - (v + \frac{1}{4})^{\dagger}$. This gives results very nearly the same as the other formula for v, but something less, particularly for small surface velocities. For instance, Du Buât's formula gives 5 inch for the mean velocity when the central surface velocity is 1 inch, whereas Dr. Young's makes it .38 inch. For large velocities both formulæ agree very closely, disregarding the difference between the measures, which is only seven per

^{*} Philosophical Transactions, 1808, p. 487.

cent. They are best suited to very small channels or pipes, but unless at mean velocities of about 3 feet per second, they are wholly inapplicable to rivers.

Prony found, from Du Buât's experiments, that for measures in metres $v = \left(\frac{2 \cdot 37187 + v}{3 \cdot 15312 + v}\right)v$, in which v is also the maximum surface velocity. This, reduced for measures in English feet, becomes

(70.)
$$v = \left(\frac{7.783 + v}{10.345 + v}\right)v;*$$

and for measures in English inches,

(71.)
$$v = \left(\frac{93.39 + v}{124.14 + v}\right)v.$$

For medium velocities v = .81 v. The experiments from which these formulæ were derived were made with small channels. We have calculated the values of v from that of v, equation (71), and given the results in columns 3, 6, and 9, in Table VII. Ximenes, Funk, and Brünning's experiments in larger channels give the mean velocity at the centre of the depth equal .914 v, when the central or maximum surface velocity is v; but as the velocity also decreases in nearly the same ratio at the surface from the centre to the sides of the channel, we shall get the mean velocity in the whole section equal

^{*} Francis, Lowell Experiments, p. 150, finds this formula to give 15 per cent. less than the result found by weir measurement from the formula $\mathbf{p} = 3.33$ $(l - 1 n h) h_2^2$, the quantity discharged being about 250 cubic feet per second, and the velocity about 3.2 feet. It appears, however, that Francis uses the mean surface velocity, and not the maximum surface velocity required by the formula: if the latter were used, the difference would be reduced to 6 per cent., or thereabouts, in equation (72).

 $\cdot 914 \times \cdot 914 \text{ v} = \cdot 835 \text{ v}$; and hence we have, for large channels,

$$v = .835 \text{ v},$$

in which equation v is the maximum velocity at the surface. We have also calculated the values of v from this formula, and given the results in columns 2, 5, and 8 of TABLE VII. This table will be found to vary considerably from those calculated from Du Buât's formula in French inches, hitherto generally used in this country, and much more applicable for all practical purposes.

MEAN BADIUS.—HYDRAULIC MEAN DEPTH.—BORDER.— COEFFICIENT OF FRICTION.

If, in the diagrams 1 and 2, Fig. 30, exhibiting the sections of cylindrical and rectangular tubes filled with flowing water, the areas be

divided respectively by the perimeters A C B D A and A B D C A, the quotients are termed "the mean radii" of the tubes, diagrams 1 and 2; and the perimeters in contact with the flowing water are termed "the borders." In the diagrams 3 and 4, the surface A B is not in contact with the channel, and the width of the bed and sides, taken together, A C D B, becomes "the border." "The mean radius" is equal to the area A B D C A divided by the length of the border A C D B. "The hydraulic mean depth" is the same as "the mean radius," this latter term being perhaps most applicable to pipes flowing full, as in diagrams 1 and 2; and the former to streams and rivers which

have a surface line A B, diagrams 3 and 4. We shall, throughout the following equations, designate the value of the "mean radius," "hydraulic mean depth,"

or quotient, area A B D C A, * by the letter r, remarking here that for cylindrical pipes flowing full, or rivers with semicircular beds, it is always equal to half the radius, or one-fourth of the diameter.

Du Buât was the first to observe that the head due to the resistance of friction for water flowing in a uniform channel increased directly as the length of the channel l, directly as the border, and inversely as the area of the cross-flowing section,† very nearly; that is, as $\frac{l}{r}$. It also increases as the square of the velocity, nearly; therefore the head due to the resistance must be proportionate to $\frac{v^2 l}{g r}$. If $c_l \times \frac{v^2 l}{2g r} = h_0$, then c_l is the coefficient for the head due to the resistance of friction, as h_l is the head necessary to overcome the friction; c_l is therefore termed "the coefficient of friction."

* M. Girard has conceived it necessary to introduce the coefficient of correction 1.7 as a multiplier to the border for finding r, to allow for the increased resistance from aquatic plants; so that, according to his reduction,

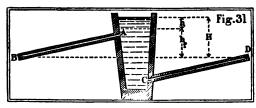

$$r = \frac{\text{area}}{1.7 \text{ border}}.$$

See Rennie's First Report on Hydraulics as a Branch of Engineering; Third Report of the British Association, p. 167; also, equation (85), p. 201.

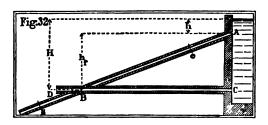

† Pitot had previously, in 1726, remarked that the diminution arising from friction in pipes is, cateris paribus, inversely as the diameters.

HYDRAULIC INCLINATION .- TRAIN.

If l be the length of a pipe or channel, and h_l the height due to the resistance of friction of water flowing in it, then $\frac{h_l}{l}$ is the hydraulic inclination. In Fig. 31 the tubes A B, C D, of the same length l, and

whose discharging extremities B and D are on the same horizontal plane B D, will have the same hydraulic inclination and the same discharge, no matter what the actual inclinations or the depth of the entrances at A and c may be, so they be of the same kind and bore: and as the velocities in A B and C D are the same, the height h due to them must be the same when the circumstances of the orifices of entry A and c are alike. We have the whole head H = h + 1 h_t (see pp. 166 and 167). The hydraulic inclination is not therefore the whole head н, divided by the length l of the pipe, as it is sometimes mistaken, but the height h_t (found by subtracting the height h, due to the entrance at A or c, and the velocity in the pipe, from the whole height) divided by the length 1. When the height h is very small compared with the whole height H, as it is in very long tubes with moderate heads, $\frac{H}{I}$ may be substituted for $\frac{h_t}{I}$ without error; but for short pipes up to 100 feet in length the latter only should be used in applying Du Buât's and some other formulæ; otherwise the results will be too large, and only fit to be used approximately in order to determine the height h from the velocity of discharge thus found. When the horizontal pipe c d, Fig. 32, is equal in every way to the inclined

pipe A B, and the head at A is that due to the velocity in CD, the discharge from the pipe A B will be equal to that from cD; but a peculiar property belongs to the pipe AB in the position in which it is here placed; for if we cut it short at any point e, or lengthen it to any extent, to E, the discharge will remain the same and equal to that through the horizontal pipe CD. The velocity in AB at the angle of inclination ABC, when AC = h_0 , and AB = CD, is therefore such that it remains unaffected by the length AE or Ae, to which it may be extended or cut short: and at this inclination the water in the pipe AB is said to be "in train." In like manner a river or stream is said to be "in train" when the inclination of its surface bears such a relation to the cross section that the mean velocity is neither decreased nor increased by the length of the channel; and we perceive from this that the acceleration caused by the inclination is exactly counterbalanced by the resistances to the motion when the moving water in a pipe or river channel is in train.

As $h = (1 + c_r) \frac{v^2}{2g}$ where c_r is the coefficient of the height due to the resistance at the orifice of entry Δ or c, and $h_t = c_t \frac{v^2 l}{2gr}$, we therefore get

(73.)
$$H = (1+c_r)\frac{v_2}{2g} + c_t \times \frac{lv^2}{2gr} = \left(1+c_r + c_{tr} \right)\frac{v^2}{2g}$$
, and hence we find the mean velocity of discharge

(74.)
$$v = \left\{\frac{2gH}{1 + c_r + c_t \frac{l}{r}}\right\}^{\frac{1}{2}} = \left\{\frac{\frac{r}{c_t} \times 2gH}{(1 + c_r)\frac{r}{c_t} + l}\right\}^{\frac{1}{2}};$$

or,

(74A.)
$$v = \left\{ \frac{2gH}{\frac{1}{c_a^3} + c_t \frac{l}{r}} \right\}^{\frac{1}{2}} = \left\{ \frac{2gHr}{\frac{r}{c_a^3} + c_t l} \right\}^{\frac{1}{2}}$$
:

as $c_4^2 = \frac{1}{c_2 + 1}$, equation (65). We have also

(74B.)
$$v = \sqrt{2g \, H} \times \left\{ \frac{1}{\frac{1}{c_a^2} + c_t \times \frac{l}{r}} \right\}^{\frac{1}{2}};$$

the values of the second member on the right hand side of this equation, or of

$$\left\{\frac{1}{\frac{1}{c_{A}^{2}}+c_{t}\times\frac{l}{r}}\right\}^{\frac{1}{2}}$$

are given, for different values of c_0 , c_4 , and $\frac{l}{r}$, in the small table at p. 152, and below at p. 191.

When h is small compared with h_i , or, which comes to the same thing, $1 + c_i$ small compared with $c_i \times \frac{l}{r}$.

(75.)
$$\mathbf{H} = c_t \times \frac{l \, v^2}{2 \, g \, r},$$

and

(76.)
$$v = \left\{ \frac{2 g r^{\frac{H}{l}}}{c_t} \right\}^{\frac{1}{2}}.$$

If, in the last equation, we substitute s for $\frac{H}{l}$, equal the sine of the angle of inclination A B C, we then have

$$(77.) v = \left\{\frac{2 g r s}{c_t}\right\}^{i}.$$

The average value of c_i for all pipes with straight channels, with velocities of about 1.5 foot per second, is .0069914, from which we find equation (77) becomes, for measures in feet,

$$(78.) v = 96 \sqrt{rs.}$$

As the mean value of the coefficient of resistance c_r for the entrance into a tube is 508, and as 2g = 64.403, and $c_t = .0069914$, equation (74), for measures in feet, becomes

$$(79.) \begin{cases} v = \left\{ \frac{64.403 \text{ H}}{1.508 + .0069914 \frac{l}{r}} \right\}^{\frac{1}{2}}, \text{ or} \\ v = \left\{ \frac{\text{H } r}{.0234 r + .0001085 l} \right\}^{\frac{1}{2}} = 100 \left\{ \frac{\text{H } r}{234 r + 1.085 l} \right\}^{\frac{1}{2}} \\ = 50 \left\{ \frac{\text{H } d}{58 d + 1.085 l} \right\}^{\frac{1}{2}}. \end{cases}$$

This, multiplied by the section, gives the discharge.

For velocities between 2 and $2\frac{1}{2}$ feet per second, $c_i = .0064403$, and therefore

$$v = \left\{ \frac{\text{H } r}{\cdot 0234 \, r + \cdot 0001 \, l} \right\}^{\frac{1}{2}} = 50 \left\{ \frac{\text{H } d}{58 \, d + l} \right\}^{\frac{1}{2}},$$

in which d = 4r =diameter of a pipe.

The following table is calculated from equation

Values of
$$\left\{\frac{1}{\frac{1}{c_a^i} + c_t \times \frac{l}{r}}\right\}^i$$

(74B) for a velocity of about 20 feet per second, when $c_t = .004556$, and for different orifices of entry, in which c_4 varies from .986 for a rounded orifice, to .715 when the pipe projects into the vessel. It gives directly the coefficient, which, multiplied by $\sqrt{2g}$ H, gives the velocity in the pipe, taking friction into account.

The small table, Section VI., p. 152, gives the like coefficients of $\sqrt{2g}$ H in equation (74B), when $c_t = 00699$ suited to a velocity of about 18 inches per second, and can be applied in like manner. The value of $\sqrt{2g}$ H is given, in inches, in column 2, Table II. For feet it is equal $8\sqrt{H}$ nearly.

DU BUAT'S FORMULA.

The coefficient of friction c_i is not, however, constant, as it varies with the velocity. That which we have just given answers for pipes when the velocity is 20 feet per second. For pipes and rivers it is found to increase as the velocity decreases; that is, the loss of head is proportionately greater for small than for large velocities. Du Buât found the loss of head to be also greater for small than large channels, and applied a correction accordingly in his formula. This, expressed in French inches, is

(80.)
$$v = \frac{297 (r^{\frac{1}{2}} - 1)}{(\frac{1}{s})^{\frac{1}{2}} - \text{hyp. log. } (\frac{1}{s} + 1.6)^{\frac{1}{2}}} - 3 (r^{\frac{1}{2}} - 1),$$

maintaining the preceding notation, in which $s = \frac{h_t}{l}$. In this formula ·1, in the numerator of the first term, is deducted as a correction due to the hydraulic

mean depth, as it was found that 297 $(r^2 - 0.1)$ agreed more exactly with experiment than 297 rt simply. The second term hyp. log. $(\frac{1}{2} + 1.6)^{t}$, of the denominator is also deducted to compensate for the observed loss of head being greater for less velocities, and the last term $\cdot 3$ ($r^{\frac{1}{2}}$ — $\cdot 1$) is a deduction for a general loss of velocity sustained from the unequal motions of the particles of water in the cross section as they move along the channel. These corrections are empirical; they were, however, determined separately, and after being tested by experiment, applied, as above, to the radical formula $v = 297 \sqrt{rs}$.

Du Buât's formula was published in his Principes d'Hydraulique, in 1786. It is, as we have seen, partly empirical, but deduced by an ingenious train of reasoning and with considerable penetration from about 125 experiments, made with pipes from the 19th part of an inch to 18 inches in diameter, laid horizontally, inclined at various inclinations, and vertical; and also from experiments on open channels with sectional areas from 19 to 40,000 square inches, and inclinations of from 1 in 112 to 1 in The lengths of the pipes experimented with varied from 1 to 3, and from 3 to 3600 feet.

In several experiments by which we have tested this formula, the resulting velocities found from it were from 1 to 5 per cent. too large for small pipes. and too small for straight rivers in nearly the same proportion. As the experiments from which it was derived were made with great care, those with pipes particularly so, this was to be expected.

riments with pipes of moderate or short lengths should have the circumstances of the orifice of entry from the reservoir duly noted; for the close agreement of this formula with them must depend a great deal, in such pipes, on the coefficient due to the height h, which must be deducted from the whole head H before the hydraulic inclination, $\frac{h_t}{l} = s$, can be obtained; but for very long pipes and uniform channels this is not necessary.

The experiments from which Du Buât's formula was constructed are given in full by the late Dr. Robinson in his able article on "rivers" in the Encyclopædia Britannica, pp. 268, 269, and 270, where the calculated and observed velocities are placed side by side in French inches per second. In all these experiments Du Buât carefully deducted the head due to the velocity and orifice of entry before finding the hydraulic inclination s, and those who attempt to calculate the velocity from the head and length of the channel only, without making this deduction, will find their calculated results very different from those there given. If there were bends, curves, or contractions, deductions would have to be made for these in like manner before finding s.

Under all the circumstances, and after comparing the results obtained from various other formulæ, we have preferred calculating tables for the values of vfrom this formula reduced for measures in English inches, which is

$$v = \frac{306.596 \ (r^{1} - .1032)}{\left(\frac{1}{s}\right)^{1} - \text{hyp. log.} \left(\frac{1}{s} + 1.6\right)^{1}} - .2906 \ (r^{1} - .1032),$$

or more simply,

(81.)
$$v = \frac{307 (r^4 - \cdot 1)}{\left(\frac{1}{8}\right)^4 - \text{hyp. log.} \left(\frac{1}{8} + 1 \cdot 6\right)^4} - \cdot 3 (r^4 - \cdot 1).$$

This gives the value of v a little larger than the original formula, but the difference is immaterial. For measures in English feet it becomes

(82.)
$$v = \frac{88.51 (r^{\frac{1}{6}} - .03)}{(\frac{1}{8})^{\frac{1}{6}} - \text{hyp. log.} (\frac{1}{8} + 1.6)^{\frac{1}{6}}} - .084 (r^{\frac{1}{6}} - .03).$$

The results of equation (81) are calculated for different values of s and r, and tabulated in Table VIII., the first eight pages of which contain the velocities for values of r varying from $\frac{1}{16}$ th inch to 6 inches; or if pipes, diameters from $\frac{1}{4}$ inch to 2 feet, and of various inclinations from horizontal to vertical. The last five pages contain the velocities for values of r from 6 inches to 12 feet, and with falls from 6 inches to 12 feet per mile.

EXAMPLE VIII. A pipe, 1½ inch diameter and 100 feet long, has a constant head of 2 feet over the discharging extremity; what is the velocity of discharge per second?

The mean radius $r = \frac{11}{4} = \frac{3}{8}$ inches, and $\frac{100}{2} = 50 = \frac{1}{s}$, is the approximate hydraulic inclination. At page 2 of Table VIII., in the column under the mean radius $\frac{3}{8}$, and opposite to the inclination 1 in 50, we find 30.69 inches for the velocity sought. This, however, is but approximative, as the head due to the velocity should be subtracted from the whole head of 2 feet, before finding the true hydraulic inclination. This

head depends on the coefficient of resistance at the entrance orifice, or the coefficient of discharge for a short tube. In all Du Buât's experiments this latter was taken at .8125, but it will depend on the nature of the junction, as, if the tube runs into the cistern, it will become as small as '715; and, if the junction be rounded into the form of the contracted vein, it will rise to .974, or 1 nearly. In this case, the coefficient of discharge may be assumed .815,* from which, in TABLE II., we find the head due to a velocity of 30.69 inches to be $1\frac{7}{8} = 1.87$ inch nearly, which is the value of h; and hence, $H = h = h_1 = 24$ -1.87 = 22.13 inches; and $\frac{l}{h_t} = \frac{100 \times 12}{22.13} = 54.2 = \frac{1}{s}$ the hydraulic inclination, more correctly. With this new inclination and the mean radius $\frac{3}{6}$, we find the velocity by interpolating between the inclinations 1 in 50 and 1 in 60, given in the table to be 30.69 - 1.34 = 29.35 inches per second. operation may be repeated until v is found to any degree of accuracy according to the formula; but it is, practically, unnecessary to do so. If we now wish to find the discharge per minute in cubic feet, we can easily do so from TABLE IX., in which, for an inch and a half pipe, we get

		0					
		Inches.			Cubic Feet	· .

The discharge found experimentally by Mr. Provis, for a tube of the same length, bore, and head, was 1.745 cubic foot per minute.

If we suppose the coefficient of discharge due to the orifice of entry and stop-cock in Mr. Provis's 208 experiments* with 1½ inch lead pipes of 20, 40, 60, 80, and 100 feet lengths, to be '715, the results calculated by the tables will agree with the experimental results with very great accuracy, and it is very probable, from the circumstances described, that the ordinary coefficient '815 due to the entry was reduced by the circumstances of the stop-cock and fixing to about '715; but even with '815 for the coefficient, the difference between calculation and experiment is not much, the calculation being then in excess in every experiment, the average being about 5 per cent., and not so much in the example we have given.

TABLE VIII. will give the velocity, and thence the discharge, immediately, for long pipes, and TABLE X. enables us to calculate the cubic feet discharged per minute, with great facility. For rivers, the mean velocity, and thence the discharge, is also found with quickness. See also TABLES XI., XII., and XIII., and the table at pp. 42 and 43.

EXAMPLE IX. A watercourse is 7 feet wide at the bottom, the length of each sloping side is 6.8 feet, the width at the surface is 18 feet, the depth 4 feet, and the inclination of the surface 4 inches in a mile; what is the quantity flowing down per minute?

^{*} Transactions of the Institution of Civil Engineers, pp. 201, 210, vol. ii.

Here
$$\frac{(18+7)\times\frac{4}{2}}{7+2\times6\cdot8} = \frac{50}{20\cdot6} = 2\cdot4272$$
 feet = 29·126 inches

 $\equiv r$, is the hydraulic mean depth; and as the fall is 4 inches per mile, we find at the 11th page of TABLE VIII., the velocity $v=12\cdot03-16=11\cdot87$ inches per second; the discharge in cubic feet per minute is, therefore,

$$50 \times \frac{11.87}{12} \times 60 = 2967.5.$$

If
$$94.17\sqrt{rs} = v$$
, we have $v = 94.17\sqrt{2.427 + \frac{1}{15840}}$

=
$$94.17 \times \sqrt{\frac{1}{6526}} = \frac{94.17}{80.7} = 1.17$$
 feet = 14.04 inches.

Watt, in a canal of the fall and dimensions here given, found the mean velocity about 13½ inches per second. This corresponds to a fall of 5 inches in the mile, according to the formula. Du Buât's formula is less by 12½ per cent. or ½th; the common formula too much by 5 per cent.

In one of the original experiments with which the formula was tested on the canal of Jard, the measurements accorded very nearly with those in this example, viz. $\frac{1}{s} = 15360$, and $r = 29\cdot1$ French inches; the observed velocity at the surface was 15·74, and the calculated mean velocity, from the formula, 11·61 French inches.* Table VII. will give 12·29 inches for the mean velocity, corre-

^{*} These measures reduced to inches, give r = 31.014, v = 12.874; and the surface velocity 16.775 inches; reduced for mean velocity 13.101 inches.

sponding to a superficial velocity of 15.74 inches. This shows that the formula also gives too small a value for v in this case, by about $\frac{1}{17}$ th of the result, it being about $\frac{1}{8.3}$ part in the other. The probable error in the formula applied to straight clear rivers of about 2 feet 6 inches hydraulic mean depth is nearly $\frac{1}{13}$ th or 8 per cent. of the tabulated velocity, and this must be added for the more correct result; the watercourse being supposed nearly straight and free from aquatic plants.

Notwithstanding the differences above remarked on, we are of opinion that the results of this formula, which we have calculated and tabulated, may be more safely relied on as applied to general practical purposes than most of those others which we shall proceed to lay before our readers. Rivers or watercourses are seldom straight or clear from weeds. and even if the sections, during any improvements. be made uniform, they will seldom continue so, as "the regimen," or adaptation of the velocity to the tenacity of the banks, must vary with the soil and bends of the channel, and can seldom continue permanent for any length of time unless protected. From these causes a loss of velocity takes place, difficult, if not impossible, to estimate accurately, but which may be taken at from 10 to 15 per cent. of that in the clear unobstructed direct channel; but be this as it may, it is safer to calculate the drainage or mechanical results obtainable from a given fall and river channel, from formulæ which give lesser, than

from those which give larger velocities. This is a principle engineers cannot too much observe.

We have before remarked, that for both pipes and rivers the coefficient of resistance increases as the velocity decreases. This is as much as to say, in the simple formula for the velocity, $v = m \sqrt{rs}$, that m must increase with v, and as some function of it. This is the case in Table VIII., throughout which the velocities increase faster than \sqrt{r} , the \sqrt{s} , or the \sqrt{rs} . In all formulæ with which we are acquainted but Du Buât's and Young's, the velocity found is constant when \sqrt{rs} or $r \times s$ is constant. In Du Buât's formula for $r \times s$ constant, v obtains maximum values between $r = \frac{3}{4}$ inch and r = 1 inch; the differences of the velocities for different values of r above 1 inch, $r \times s$ being constant, are not much. We may always find the maximum value, or nearly so, by assuming $r = \frac{3}{4}$ inch, and finding the corresponding inclination from the formula $\frac{4rs}{3}$, which is equal to it. For example, if r = 12 inches, and s = $\frac{1}{10560}$, the velocity is found equal 9.52 inches; but when rs is constant, the inclination s corresponding to $r = \frac{3}{4}$ inch is $\frac{4 \times 12^{n}}{8 \times 10560} = \frac{1}{660}$, from which we find from the table v = 10.25 inches for the maximum velocity, making a difference of fully 7 per cent.

When r = 01 of an inch, or a pipe is $\frac{1}{15}$ th part of an inch in diameter, Du Buât's formula fails, but it gives correct results for pipes $\frac{1}{5}$ th of an inch in diameter, and two of the experiments from which it

was derived were made with pipes 12 inches long and only 1sth part of an inch in diameter.

Coulomb having shown that the resistance opposed to a disc revolving in water increases as the function $av + bv^2$ of the velocity v, we may assume that the height due to the resistance of friction in pipes and rivers is also of this form; and that

(83.)
$$h_{t} = (a v + b v^{2}) \frac{l}{r},$$

and consequently,

(84.)
$$rs = av + bv^{s}$$
, and $v = \left\{\frac{rs}{b} + \frac{a^{3}}{4b^{2}}\right\}^{\frac{1}{2}} - \frac{a}{2b}$.

Girard first gave values to the coefficients a and b. He assumed them equal, and each equal to 0003104 for measures in metres, and thence the velocity in canals,

(85.)
$$v = (3221.016 \, rs + .25)^3 - .5;*$$

which reduced for measures in English feet becomes

(86.)
$$\begin{cases} v = (10567.8 \, r \, s + 2.67)^{\frac{1}{2}} - 1.64, \text{ or } \\ v = 103 \, \sqrt{r \, s} - 1.64, \text{ nearly.} \end{cases}$$

The value of a = b = .0003104 was obtained by means of twelve experiments by Du Buât and Chezy. Of course the value is four times this in the original, as we use the mean radius in all the formulæ instead of the diameter. This formula is only suited for very small velocities in canals, between locks, containing aquatic plants; it is inapplicable to rivers and channels in which the velocity exceeds an inch per second.

Prony found from thirty experiments on canals,

[•] See Brewster's Encyclopedia, Article Hydrodynamics, p. 259.

that a = .000044450 and b = 000309314,* for measures in metres, from which we find

(87.)
$$v = (3232.96 \, rs + .00516)^{4} - .0719$$
; this reduced for measures in English feet is,

(88.)
$$\begin{cases} v = (10607 \cdot 02 \, rs + \cdot 0556)^{\frac{1}{2}} - \cdot 236 ; † \text{ or } \\ v = 103 \, \sqrt{rs} - \cdot 24 \text{ nearly :} \end{cases}$$

the velocities did not exceed 3 feet per second in the experiments from which this was derived.

For pipes, Prony found,‡ from fifty-one experiments made by Du Buât, Bossut, and Couplet, with pipes from 1 to 5 inches diameter, from 30 to 7,000 feet in length, and one pipe 19 inches diameter and nearly 4,000 feet long, that a = .00001733, and b = .0003483, from which values

(89.) $v = (2871 \cdot 09 \, rs + \cdot 0006192)^{1} - \cdot 0249$, for measures in metres, and for measures in English feet,

(90.)
$$\begin{cases} v = (9419.75 \ rs + .00665)^{\frac{1}{2}} - .0816; \text{ or } \\ v = 97 \sqrt{rs} - .08 \text{ nearly.} \end{cases}$$

Prony also gives the following formula applicable to pipes and rivers. It is derived from fifty-one selected experiments with pipes, and thirty-one with open channels:

(91.)
$$v = (3041.47 \, rs + .0022065)^{1} - .0469734,$$

for measures in metres, which, reduced for measures in English feet, is

(92.)
$$\begin{cases} v = (9978.76 \, rs + .02375)^{\frac{1}{2}} - .15412; \text{ or } \\ v = 100 \, \sqrt{rs} - .15 \text{ nearly.} \end{cases}$$

EYTELWEIN, following the method of investigation pursued previously by Prony, found from a large number of experiments, a = 0000242651, and b = 000365543 in rivers, for measures in metres; and, therefore,

(93.) $v = (2735.66 \, r \, s + .001102)^{i} - .0332.*$ This reduced for measures in English feet, is

(94.)
$$\begin{cases} v = (8975.43 \, r \, s + .0118858)^{\frac{1}{2}} - .1089; \text{ or } \\ v = 94.5 \, \sqrt{r \, s} - .11 \text{ nearly } = 1.3 \, \sqrt{f \, r} - .11 \\ = \sqrt{1.7 \, f \, r} - .11 \end{cases}$$

when f is the fall in feet per mile. He also shows,† that $\frac{1}{1}$ ths of a mean proportional between the fall in two English miles and the hydraulic mean depth, gives the mean velocity very nearly. This rule for measures in inches is equivalent to

(95.)
$$v = 324 \sqrt{rs}$$
:

and for measures in feet

$$(96.) v = 93.4 \sqrt{rs}.$$

For the velocity of water in pipes, he found,‡ from the fifty-one experiments of Du Buât, Bossut, and

page 164, Third Report, British Association, by Rennie; and at pages 427 and 533, Article Hydrodynamics, Brewster's Encyclopedia. This reduction, $v = -0.1541 + (.02375 + 32806.6 rs)^4$ is entirely incorrect; and, being the same in each of those works, appears to have been copied one from the other.

- Mémoires de l'Académie de Berlin, 1814 et 1815. See equation (110).
 - † Handbuch der Mechanik und der Hydraulik, Berlin, 1801.
 - 1 Mémoires de l'Académie des Sciences de Berlin, 1814 et 1815.

Couplet, that a = .0000223, and b = .0002803, from which we get for measures in metres,

(97.)
$$v = (3567 \cdot 29 \, r \, s + 0.0157)^{\frac{1}{2}} - 0.0397$$
; which reduced for measures in English feet becomes (98.)
$$\begin{cases} v = (11703 \cdot 95 \, r \, s + 0.01698)^{\frac{1}{2}} - 0.0393 \\ v = 108 \, \sqrt{r \, s} - 0.01898 \end{cases}$$

Another formula given by Eytelwein for pipes, which includes the head due to the velocity for the orifice of entry, is

(99.)
$$v = 50 \left(\frac{d H}{l + 50 d} \right)^{\frac{1}{2}};$$

in which H is the head, l the length, and d the diameter of the pipe, all expressed in English feet. This is a particular value of equation (74) suited to velocities of about $2\frac{1}{2}$ feet per second. It must be here mentioned, that much of the valuable information presented by Eytelwein is but a modification of what Du Buât had previously given, to whom only for much that is attributed to the former we are primarily indebted.

In the foregoing as well as in the following equations for the velocity, we have, unless otherwise stated, maintained one class of standards. It is evident if we change these standards in part, or in whole, that apparently different forms of the equations will arise; thus—if for s, the hydraulic inclination, we substitute $\frac{m}{5280}$, we shall have the fall m in feet per mile, in place of the inclination s; so that equation (94), for instance, would become $v = (1.7 mr + .012)^{t} - .11 = (1.7 mr)^{t} - .11$ nearly, in which v is the velocity in feet per second, m the

fall in feet per mile, and r the "hydraulic mean depth" in feet. In like manner equation (98) would become

$$v = (2 \cdot 2 m r + \cdot 02)^{\frac{1}{2}} - \cdot 13 = (2 \cdot 2 m r)^{\frac{1}{2}} - \cdot 13.$$

The first of these reductions, viz.:—

$$v = (1.7 m r + .0119)^{\frac{1}{2}} - .109$$

is given in a book of tables calculated for river channels for the Commissioners of Public Works, Ireland, the original equation being Eytelwein's, and not D'Aubuisson's, who merely copied it, and is suited for velocities averaging about 1.3 feet per second.

Mr. Hawksley gives for pipes the formula

$$v_{y} = .77 \left\{ \frac{d_{i} H_{i}}{l_{y} + 1.5 d_{i}} \right\}^{\frac{1}{2}},$$

in which l is the length in yards, H the head in inches, d the diameter in inches, and v the velocity in yards per second. For uniform feet measures, for, v, d, and H, this becomes

$$v = 48.045 \left\{ \frac{d \text{ H}}{l + 54 d} \right\}^{\frac{1}{2}}$$
,

which is only Eytelwein's equation (99) slightly modified. Eytelwein's equation expressed in the measures used by Mr. Hawksley would be very nearly

$$v_y = .8 \left\{ \frac{d_i H_i}{l_y + 1 \frac{1}{2} d_i} \right\}^{\frac{1}{2}},$$

which is far the simplest of the two; both, however, are but particular cases of the general equation 74, and only suited for velocities of about 2½ feet per second.

Dr. Thomas Young* also derives his formula from

^{*} Philosophical Transactions for 1808.

the supposition, that the head due to the resistance of friction assumes the form of equation (83); calling the diameter of a pipe d, he takes

$$h_i = (a v + b v^2) \frac{l}{d},$$

and the whole height $H = h_t + \frac{v^2}{586}$, expressed in inches. He found from some experiments of his own, those collected by Du Buât, and some of Gerstner's, that

(100.)
$$a = .0000002 \left\{ \frac{900 d^3}{d^3 + 1136} + \frac{1}{d^3} \left(1085 + \frac{13.21}{d} + \frac{1.0563}{d^3} \right) \right\};$$

and

(101.)
$$b = 0000001 \left\{ 413 + \frac{75}{d} - \frac{1440}{d + 12 \cdot 8} - \frac{180}{d + 355} \right\};$$

then as $\frac{1}{586} = .00171$, we get

(102.)
$$v = \left\{ \frac{H d}{b l + 0.0171 d} + \left(\frac{a l}{2 b l + 0.0341 d} \right)^{2} \right\}^{1} - \frac{a l}{2 b l + 0.0341 d}.$$

When the length l of the pipe is very great compared with the head due to the orifice of entrance and velocity, $00171 v^2$, we have

(103.)
$$v = \left\{ \frac{H}{b} \frac{d}{l} + \frac{a^2}{4b^2} \right\}^{\frac{1}{2}} - \frac{a}{2b};$$

or by substituting for l its value s, equal the sine of the inclination.

(104.)
$$v = \left\{\frac{s d}{b} + \frac{a^2}{4 b^3}\right\}^{\frac{1}{2}} - \frac{a}{2 b}$$

The values of a and b are for measures in inches. For most rivers, in which d must be taken equal 4r, he finds for French inch measures, $v = \sqrt{20000 ds}$; this reduced for English inches is

$$(105.) v = 292\sqrt{rs};$$

which again reduced for feet measures, becomes

$$(106.) v = 84.3\sqrt{rs}.$$

These latter values, for rivers, are even smaller than those found from Du Buât's formula; less than the observed velocities, and less than those found from any other formula, with the exception of Girard's. The values of the coefficients a and b vary in this formula with the value of d=4r; they are expressed generally in equations (101) and (102), from which we have calculated the following table for different values of d and r.

An examination of this table will show that a obtains a minimum value when d is between 10 and 11 inches; and b when the diameter is between $\frac{1}{2}$ and $\frac{3}{4}$ of an inch. Now, it appears from equation (102), that v increases with $\sqrt{\frac{Hd}{bl}}$ nearly, or, which is the same thing, as b decreases, there must, cateris paribus, be a maximum value of v for a given value of $\frac{Hd}{l}$, or rs, when d is between $\frac{1}{2}$ and $\frac{3}{4}$

inch; but as $\frac{a}{2b}$ has a minimum value when d is nearly 12 inches, the maximum value of v referred to will be found between values of d from $\frac{a}{2}$ inch to 12 inches; in fact, when d = 10 inches nearly. We have already pointed out a similar peculiarity in Du

Buât's general theorem, at page 195. It will not be necessary to take out the values of $\frac{a}{2b}$ and $\frac{a^2}{4b^2}$ to more than one place of decimals.

The values of $\frac{a}{2b}$ are also given in the following table, and may be used in equation (104) for finding the discharge from long pipes. It is, however, necessary to remark, that this equation is sometimes misapplied in finding the velocity from short pipes, and those of moderate lengths. It is necessary to use equation (102), which takes into consideration the head due to the velocity and orifice of entry for such pipes.

For a pipe 11 inches in diameter, the expression for the velocity, equation (104), becomes for inch measures,

$$v = \left\{ \frac{sd}{.000034} + 1.49 \right\}^{1} - 1.22$$
:

and for feet measures, also substituting 4 r for d,

(106A.)
$$v = \left\{\frac{sr}{\cdot 000102}\right\}^{1} - 1 = 100 (rs)^{1} - 1$$

very nearly. For a pipe ·7 inch in diameter we should find in a like manner for feet measures,

(106B.)
$$v = 118 (rs)^{\frac{1}{2}} - 5$$
,

which is only suitable for pipes with very high velocities.

SIR JOHN LESLIE states,* that the mean velocity of a river in miles per hour, is 18ths of the mean proportional between the hydraulic mean depth and

^{*} Natural Philosophy, p. 423.

TABLE OF THE VALUES OF $a, b, \frac{a}{3}b$, and $\frac{a^3}{4b^3}$ in equation (104).

the fall in two miles in feet. This rule is equivalent, for measures in feet, to

(107.)
$$v = 100 \sqrt{rs}$$
;

and is applicable to rivers with velocities of about 2½ feet per second.

D'Aubuisson, from an examination of the results obtained by Prony and Eytelwein, assumes* for measures in metres that a = .0000189, and b = .0003425 for pipes, substituting these in equation (84) and resolving the quadratic

(108.)
$$v = (2919.71 \, rs + .00074)^{\frac{1}{2}} - .027$$
; which reduced for measures in English feet becomes

(109.)
$$\begin{cases} v = (9579 \, rs + .00813)^{\frac{1}{2}} - .0902, \text{ or} \\ v = 98 \, \sqrt{rs} - .1 \text{ nearly.} \end{cases}$$

For rivers he assumes with Eytelwein,† a = 000024123 and b = 0003655, for measures in metres, and hence

(110.)
$$v = (2735.98 \, rs + .0011)^{\frac{1}{2}} - .033$$
; which for measures in English feet is

(111.)
$$\begin{cases} v = (8976.5 \, rs + .012)^{\frac{1}{2}} - .109, \text{ or} \\ v = 94.5 \, \sqrt{rs} - .11 \text{ nearly.} \end{cases}$$

When the velocity exceeds two feet per second, he assumes, from the experiments of Couplet, a = 0, and b = .00035875; these values give

(112.)
$$v = \sqrt{2787.46 \, rs}$$

for measures in metres, and

(113.)
$$v = 95.6 \sqrt{rs} = \sqrt{9145 rs}$$

for measures in English feet. Equations (110) and (111) are the same as (93) and (94), found from Eytel-

^{*} Traité d'Hydraulique, p. 224.

[†] Traité d'Hydraulique, p. 138. See Equation (98).

wein's values of a and b, and it may be remarked that D'Aubuisson's equations for the velocity generally, are simply those of Prony and Eytelwein.

The values which we have found to agree best with experiments on clear straight rivers are a = .0000035, and b = .0001150 for measures in English feet, from which we find

(114.)
$$\begin{cases} v = (8695 \cdot 6 \ rs + \cdot 00023)^{i} - \cdot 0152, \text{ or} \\ v = 93 \sqrt{rs} - \cdot 02, \end{cases}$$

which for an average velocity of $1\frac{1}{2}$ foot per second will give $v = 92 \cdot 3 \sqrt{rs}$ nearly, and for large velocities $v = 93 \cdot 3 \sqrt{rs}$; for smaller velocities than $1\frac{1}{2}$ foot per second, the coefficients of \sqrt{rs} decrease pretty rapidly. This formula will be found to agree more accurately with observation and experiment than any other we know of this form.

WEISBACH is perhaps the only writer who has modified the form of the equation $rs = a v + b v^2$. In Dr. Young's formula, a and b vary with r, but Weisbach assumes that $h_r = \left(a + \frac{b}{v^3}\right) \frac{l}{a} \times \frac{v^2}{2g}$, and finds from the fifty-one experiments of Couplet, Bossut, and Du Buât, before referred to, one experiment by Guemard, and eleven by himself, all with pipes varying from an inch to five and a half inches in diameter, and with velocities varying from $1\frac{1}{2}$ inch to 15 feet per second, that a = .01439, and b = .0094711 for measures in metres; hence we have for the metrical standard

(115.)
$$h_t = \left(0.01439 + \frac{0.0094711}{v^4}\right) \frac{l}{d} \times \frac{v^3}{2g}.$$

This reduced for the mean radius r is

(116.)
$$h_r = \left(.003597 + \frac{.0023678}{v^4}\right) \frac{l}{r} \times \frac{v^2}{2g};$$
 from which we find for measures in English feet

(117.)
$$h_t = \left(003597 + \frac{0042887}{v^4}\right) \frac{l}{r} \times \frac{v^2}{2g},$$

and thence

(118.)
$$rs = (.003597 + \frac{.0042887}{v^i}) \frac{v^2}{2g};$$

and by substituting for 2g, its value 64.403,

(119.)
$$rs = (00005585 + \frac{00006659}{v^4})v^2$$
.

In equation (117), $(.003597 + \frac{.0042887}{...}) = c_t$ is the coefficient of the head due to friction. The equation does not admit of a direct solution, but the coefficient should be first determined for different values of the velocity v and tabulated, after which the true value of v can be determined by finding an approximate value, and thence taking out the corresponding coefficient from the table, which does not vary to any considerable extent for small changes of velocity. In the following small table we have calculated the coefficients of friction, and also those of v^2 , in equation (119), for different values of the velocity v.

If the value of $\frac{64\cdot 4}{c_t}$ here found, be substituted in the equation $v = \sqrt{\frac{64\cdot 4}{c_t}} rs$, we shall have the value of v. According to this table the coefficient of friction for a velocity of six inches is more than twice that for a velocity of twenty feet, and the velocity is less in the proportion of 81·6 to 118·9, or of 81·6 $(rs)^{1}$

to $118.9 (rs)^3$. On comparing these coefficients and those for pipes in the preceding formulæ, with those for rivers of the same hydraulic depth, we perceive that the loss from friction is greatest in the latter, as might have been anticipated; but this evidently arises from lesser velocities.

It has been already remarked that the coefficient of friction decreases as the velocity increases. only general formula which properly meets this defect in the common formulæ is Weisbach's, but it does not give the velocity v directly, as this quantity is involved in both sides of his equation. As for several hydraulic works it is necessary to convey water through pipes to work machines under high heads, and for which the common formula would give results considerably under the true ones, it appeared to me desirable to obtain some simple expression for the velocity which might be easily remembered and applied, which would be equally correct with other formulæ for medium velocities of from one to two and a half feet, and which at the same time would give practically correct results for lesser and greater velocities within the limits of experiment. By reducing the velocity found from experiment to the form $v = m \sqrt{r_s}$ for every case, and afterwards applying a correction of the form $n \sqrt[3]{rs}$ to meet the increasing value of m as v increased, I discovered that the expression

(119A)
$$v = 140 (rs)^{\frac{1}{2}} - 11 (rs)^{\frac{1}{2}}$$

gave results not differing more from experiments than these frequently do from each other. The following table exhibits the velocities compared with those obtained from the experiments made by Du Buât, Couplet, Watt, Mr. Provis, and Mr. Leslie, in the Minutes of the Institution of Civil Engineers for February 1855. The last experiment was furnished to me by Mr. Hodson of Lincoln. Numbers 34 and 35 were made by myself, and give the mean results of several experiments made with great care; the coefficient of the orifice of entry was found to be .860.* The measures have been all reduced to English feet. The results found by the same experimenters, at the same time, with the same apparatus, sometimes differ by three or four per cent., as may be seen by referring to Mr. Provis' experiments, (Transactions of the Institution of Civil Engineers, vol. II., p. 203,) and the difference in the experiments shown in the table are apparent. The difference in the velocities found from the experiments, do not exceed those inseparable from practical investigations, and they differ as much in themselves as from the formula, which for cylindrical pipes of diameter d may be thus expressed,

(119B.)
$$\begin{cases} v = 70 \ (d \ s)^{\frac{1}{2}} - 6.93 \ (d \ s)^{\frac{1}{3}}, \text{ or } \\ v = 70 \ (d \ s)^{\frac{1}{2}} - 7 \ (d \ s)^{\frac{1}{3}} \text{ nearly.} \end{cases}$$

The expression fails when $70 \ (d\ s)^{\frac{1}{3}}$ is equal to or less than $6.93 \ (d\ s)^{\frac{1}{3}}$, but as this only happens when $r\ s = \left(\frac{11}{140}\right)^6 = .000000235$, and for velocities below one inch per second, its practical value is not thereby affected. The expression of Du Buât fails with a

[•] The coefficient for the orifice of entry was found by cutting off the pipe at two diameters from the cistern at the conclusion of the experiments, and finding the time of emptying. *Vide* p. 177.

TABLE showing the Experimental Results of observed Velocities in Water Channels, with the Author's general formula for Pipes and Rivers, viz. $v = 140 \ (r \ s)^{\frac{1}{2}} - 11 \ (r \ s)^{\frac{1}{2}}$.

tube of one twenty-fifth part of an inch in diameter, no matter what the head may be, as it then makes the velocity equal to nothing, although some of the experiments from which it was derived were made with tubes but the eighteenth part of an inch diameter. The following expression is free from this defect:

(119c.)
$$v = 60 (rs)^{\frac{1}{2}} + 120 (rs)^{\frac{2}{3}},$$

and will give results approximating very closely to those found from Du Buât's formula, and, therefore, with those experiments with which it most nearly coincides, but agreeing much more closely with Watt's and other experiments, on rivers. It gives higher results than the previous formula for velocities below six inches, but the results found by different experimenters differ very much in those. For higher velocities it appears to differ occasionally only about one-twentieth from observation, being in general less, as far as twenty feet per second, where it coincides very closely with Mr. Hodson's experiment. As the errors appear to be of an opposite kind generally, in the two last expressions, we may get by combining them

(119p.)
$$v = 100 (rs)^{\frac{1}{2}} + 60 (rs)^{\frac{2}{3}} - 5.5 (rs)^{\frac{1}{3}}$$

an expression which, however, wants simplicity for ready practical application. When the length of the pipe does not exceed from 1000 to 2000 diameters, a correction is due to the velocity in it, and to the orifice of entry before finding the "hydraulic inclination" (s). The coefficient used in reducing the foregoing experiments for the orifice of entry was $\cdot 815$, which gives $1.508 \frac{v^2}{2g}$ for the height due to the joint effects of velocity and orifice. This must be deducted from the head (H) before dividing it by the length (l) to find the inclination (s) in our table.

The following table, calculated from the formula (119A), $v = 140 \ (r \, s)^{\frac{1}{2}} - 11 \ (r \, s)^{\frac{1}{3}}$, gives the corresponding values of $r \, s$ and v, so that when one is known the other is immediately found from inspection. Thus, if $r \, s = .03125$, we find

v = 20.6 when rs = .029167v = 24.7 when rs = .041666

Difference 4·1 corresponds to ·012499 ·03125

.02917

Difference ·00208

Whence $0125:4\cdot1::00208:\cdot7$ nearly, and $20\cdot6+7=21\cdot3$ is the velocity sought; the same practically as found in Example 26, p. 37. If allowance is to be made for the head due to the orifice of entry and velocity, this head can be determined from the velocity due to the value of rs in the table next less than the given value with sufficient accuracy. In this case, this velocity is $20\cdot6$ feet per second = 247 inches nearly. If the orifice of entry be square, the coefficient is $\cdot815$, and the head due to the velocity and this coefficient is, Table II., 10 feet nearly. If r be known separately, and also s, as well as the head r, and the length of the pipe r, we had at first

 $\frac{H}{l} = s$, and, therefore, $\frac{H-10}{l} = \frac{h}{l} = s$.

In Example 26, p. 37, H = 150, and l = 100 feet, therefore, the new value of $\frac{h}{l} = \frac{140}{100}$ is 1.4; and as r must be equal 020833, rs = 02917: the value

TABLE for finding the Velocity in feet per second, from the product of the hydraulic mean depths and hydraulic inclinations, and the reverse calculated from the Author's formula $v = 140 \ (rs)^{\frac{1}{2}} - 11 \ (rs)^{\frac{1}{2}}$, in which r, s, and v, are feet measures.

corresponding to which, in our table, is 20.6, the velocity when allowance is made for the head due to the velocity and orifice of entry.

In general, by taking the value of v for the next less value of r s in the table, we shall find the velocity with sufficient accuracy, and also the value of r s from that of v by taking it as the next greater. If we had taken r s = .0008523, the table would give v = 3.04 feet, the same practically as already found in Example 27, p. 38.

The value of r s, when known, determines the value of v. If r be assumed of any convenient dimensions, s is determined; and, in like manner, any suitable value of s determines r; thus:

$$\frac{r s}{r} = s$$
, and $\frac{r s}{s} = r$.

It is well to remark, here again, that for pipes the value of r is the fourth part of the diameter d, and that

$$r=\frac{d}{A}$$
, and $4 r=d$.

In 1857, M. Darcy, inspecteur des ponts et chausées, published his Recherches expérimentales relatives au Mouvement de l'Eau dans les Tuyaux,* the result of 198 experiments, in which the velocities varied from 03 to 5 or 6 métres per second, or from 1½ inch to 16 or 19 feet, and with pipes varying from ½ inch to 20 inches diameter. The formula by which he presents the results is in métres,

$$\mathbf{R} \mathbf{J} = b_1 \mathbf{U}^2,$$

in which R is the radius of the pipe, J the hydraulic

^{*} Morin's Hydraulique, deuxième édition, Paris, p. 164.

inclination, b_1 a variable coefficient dependent on the circumstances, and v the velocity per second. For wrought and cast iron pipes of the same state of bore, the value of b_1 is expressed by M. Darcy, by the equation

$$b_1 = .000507 + \frac{.00000647}{R},$$

the agreement between which and experiment is shown in the following table.

Diameters in English inches.	Diameters in métres.	Values of b ₁ from experiments.	Values of b ₁ by the formula.	Remarks.

For iron coated with bitumen, the value of b_1 in a pipe ·196 métres in diameter was ·0004334; for a newly cast pipe of ·188 métres, b_1 was ·000584; and for a pipe ·2432 métres in diameter, b_1 was ·001168; the relative proportions of b_1 in these three instances, being as

1.1 to 1.5 and to 3:

and, therefore, the velocities, or discharges, would be inversely as the square roots of these, or as

By substituting our notation for that of M. Darcy, we shall have in métres, from equations (a) and (b),

$$rs = \frac{b_1}{2}v^2 = \left\{ 0002535 + \frac{0000016175}{r} \right\}v^2;$$

which for feet measures becomes (as 1 métre = 3.281 feet)

$$rs = \left\{ 0002535 + \frac{3.281 \times 0000016175}{r} \right\} \times \frac{v^s}{3.281}$$
:

hence we get

$$v^{2} = \left\{ \frac{rs}{\cdot 00007726 + \frac{\cdot 00000162}{r}} \right\},$$

and, therefore,

$$v = \left\{ \frac{rs}{.00007726 + \frac{.00000162}{r}} \right\}^{\frac{1}{2}}.$$

For all half-inch pipes this becomes

$$v = \left\{\frac{rs}{.00023278}\right\}^{\frac{1}{2}} = 65.5 \sqrt{rs};$$

for all inch pipes,

$$v = \left\{\frac{rs}{.00015502}\right\}^{\frac{1}{2}} = 80.3 \sqrt{rs};$$

for all two-inch pipes,

$$v = \left\{\frac{rs}{.00011614}\right\}^{\frac{1}{2}} = 92.8 \sqrt{rs};$$

for all four-inch pipes,

$$v = \left\{\frac{rs}{.0000967}\right\}^{\frac{1}{2}} = 101.7 \sqrt{rs};$$

for all six-inch pipes,

$$v = \left\{ \frac{rs}{.00009022} \right\}^{\frac{1}{2}} = 105.3 \sqrt{rs};$$

for all nine-inch pipes,

$$v = \left\{\frac{rs}{.0000859}\right\}^{\frac{1}{2}} = 107.8 \sqrt{rs};$$

for all twelve-inch pipes,

$$v = \left\{ \frac{rs}{.00008374} \right\}^{\frac{1}{2}} = 109.3 \sqrt{rs};$$

for all eighteen-inch pipes,

$$v = \left\{\frac{rs}{.00008158}\right\}^{\frac{1}{2}} = 110.7 \sqrt{rs};$$

for all twenty-four-inch pipes,

$$v = \left\{ \frac{rs}{.0000805} \right\}^{\frac{1}{2}} = 111.5 \sqrt{rs};$$

and when r is large, as for very large pipes and channels, we get the velocity

$$v = \left\{ \frac{rs}{.00007726} \right\}^{\frac{1}{2}} = 113.8 \sqrt{rs}.$$

There is evidently, on an examination of these results, a great error in the formula of M. Darcy. As long as the diameter of a long pipe continues constant, the velocity is always represented by a given fixed multiple of \sqrt{rs} , or of the square root of the product of the hydraulic inclination and hydraulic mean depth, no matter how small or great the velocity in the pipe may be. For an inch pipe this multiplier for feet measures is 80.3. Now with a lead pipe I have found, from several experiments, that for a velocity of about 15 feet per second, the multiplier to be 117 or 118; and for a velocity of about 22 feet per second, Mr. Hodson's experiment gives a multiplier of about 120. Taking the other

extreme for large pipes, the multiplier derived from M. Darcy's formula is 113.8, no matter how small the velocity may be. Now we have experiments in abundance to prove that for velocities of about 12 or 13 inches per second, the multiplier cannot exceed 95. We, therefore, look upon these researches of M. Darcy as partial and defective, and his formula as a representation, at best, of a limited range of velocities, in which those at either side are omitted or not perceived.

For small pipes, any obstruction arising from defective bore, decomposition, encrustation, or from diminished bore, affects the discharge much more considerably than the same obstructions in a large pipe. In order to compare correctly the effects of the state of the bore on the discharge, we must use pipes of exactly the same diameter, and determine the value of b_1 from experiments in which the velocity is the same, otherwise the results, as deduced by M. Darcy and given by Morin, cannot be depended upon.

COEFFICIENTS DUE TO THE ORIFICE OF ENTRY .-- PROBLEMS.

Unless where otherwise expressed, the head due to the velocity and orifice of entry is not considered in the preceding equations. In equation (74), where it is taken into calculation generally,

$$v = \left\{ \frac{2gH}{1 + c_r + c_t \times \frac{l}{r}} \right\}^{\frac{1}{2}}$$

in which $1 + c_r$ is equal to $\binom{1}{c}^3$, c_r being the coefficient

of resistance due to the orifice of entry, and c_r the coefficient of velocity or discharge from a short tube. If the tube project into the reservoir, and be of small thickness, c_r will be equal 715 nearly, and therefore $c_r = .956$; if the tube be square at the junction, the mean value of c_r will be .814, and therefore $c_r = .508$; and if the junction be rounded in the form of the contracted vein, c_r is equal to unity very nearly, and $c_r = 0$. For other forms of junction the coefficients of discharge and resistance will vary between these limits, and particular attention must be paid to their values in finding the discharge from shorter tubes and those of moderate lengths; but in very long tubes

 $1 + c_r$ becomes very small compared with $c_t \times \frac{t}{r'}$, and may be neglected without practical error. These remarks are necessary to prevent the misapplication of the tables and formulæ, as the height due to the velocity and orifice of entry is an important element in all calculations for short tubes.

We have considered it unnecessary to give any formulæ for finding the discharge itself, because, the mean velocity once determined, the calculation of the discharge from the area of the section is one of simple mensuration; and the introduction of this element into the three problems to which this portion of hydraulic engineering applies itself, renders the equations of solution complex, though easily derived; and presents them with an appearance of difficulty and want of simplicity which excludes them, nearly altogether, from practical application. The three problems are as follows:—

I. Given the fall, length, and diameter of a pipe or hydraulic mean depth of any channel, to find the discharge.

Here all that is necessary is to find the mean velocity of discharge, which, multiplied by the area of the section (equal $d^2 \times 7854$ in a cylindrical pipe), gives the discharge sought. Table VIII. gives the velocity at once for long channels, according to Du Buât, or it can be found from equation (119A) by calculation. Table IX. gives the discharge in cubic feet per minute for different diameters of pipes, and velocities in inches per second, when found from Table VIII. or formula (119A). See also Tables XI. and XII. For a pipe 6 inches in diameter, the velocity per second is practically equal to the discharge in cubic feet per minute. See also the tables, pp. 42, 43, 252, and 253.

II. Given the discharge and cross section of a channel, to find the fall or hydraulic inclination.

If the cross section be circular, as in most pipes, the hydraulic mean depth is one-fourth of the diameter; in other channels it is found by dividing the water and channel line of the section, wetted perimeter, or border, into the area. The velocity is found by dividing the area into the discharge, and reducing it to inches per second; then in TABLE VIII., under the hydraulic mean depth, find the velocity, corresponding to which the fall per mile will be found in the first column, and the hydraulic inclination in the second. This result can be corrected by trial and error to accord with formula (119A), and the table for the values of rs and v, p. 220,

calculated from it. See also the tables, pp. 42, 43, 252, and 253.

III. Given the discharge, length, and fall, to find the diameter of a pipe, or hydraulic mean depth and dimensions of a channel.

This is the most useful problem of the three. Assume any mean radius r_a , and find the discharge D_a by Problem I. We shall then have for cylindrical pipes

$$r_{a}^{\frac{5}{2}}:r^{\frac{5}{2}}::D_{a}:D::1:\frac{D}{D_{a}};$$

and as r_a , p, and p_a are known, $r^{\frac{5}{2}}$ becomes also known, and thence r. Table XIII. will enable us to find r with great facility. Thus, if we had assumed $r_a = 1$ and found $p_a = 15$, $p_$

$$1:r^{\frac{5}{2}}::1:\frac{38}{15}::1:2\cdot 2$$
, therefore $r^{\frac{5}{2}}=2\cdot 2$;

and thence by Table XIII., r = 1.37, the mean radius required, four times which is the diameter of the pipe. For other channels, the quantity thus found must be the hydraulic mean depth; and all channels, however varied in the cross section, will have the same velocity of discharge, when the fall, length, and hydraulic mean depth are constant. If r_* be assumed equal to $1\frac{1}{2}$ inch, the velocity found from Table VIII. will then be the discharge in cubic feet per minute nearly, and this "mean radius" can always be assumed for the first term of the proportion. See also the tables, pp. 42, 43, 252, and 253.

In order to find the dimensions of any polygonal channel whatever, which will give a discharge equal to D, we may assume any channel similar to that proposed, one of whose known sides is s_a , and find the corresponding discharge, D_a , by Problem I., or from Tables XI. and XII.; then, if we call the like side of the required channel, s, we shall have $s = s_a \left(\frac{D}{D_a}\right)^{\frac{3}{2}}$, and thence the numerical value from Table XIII. The result, as before, can be corrected to accord with any of our formulæ by the method of trial and error.

As it frequently happens that deposits in and encrustations on a pipe take place from time to time, which diminish the flowing section considerably, it is always prudent, when calculating the necessary diameter, to take the largest coefficient of friction, c_n or to double its mean value, particularly for small pipes, when calculating the diameter from any of the formulæ. Some engineers, as D'Aubuisson, increase the quantity of water by one-half to find the diameter; but much must depend on the peculiar circumstances of each case, as sometimes less may be sufficient, or more necessary. The discharge increases in similar figures, nearly as $r^{\frac{5}{2}}$ or as $d^{\frac{5}{2}}$, that is, as the square root of the fifth power of the diameter, and the corresponding increase in the diameter for any given or allowed increase in the discharge can be easily found by means of TABLE XIII., as shown above. If we increase the dimensions by one-sixth, the discharge will be increased by one-half nearly, and by doubling them the discharge is increased in the proportion of 5\forall to 1.

For shorter pipes, we have to take into consideration the head due to the velocity and orifice of entry.

Taking the mean coefficient of velocity or discharge, we find from TABLE II. the head due to the velocity, if it be known; this subtracted from the whole head, H, leaves the head, h_t , due to the hydraulic inclination, which is that we must make use of in the table. If the velocity be not given, we can find it approximately; the head found for this velocity, due to the orifice of entry, when deducted, as before, will give a close value of h_t , from which the velocity may be determined with greater accuracy, and so on to any degree of approximation. In general, one approximation to h, will be sufficient, unless the pipes be very short, in which case it is best to use equation (74). Example VIII., p. 195, and the explanation of the use of the tables, Section I., may be usefully referred to

TABLES XI., XII., and XIII. enable us to solve with considerable facility all questions connected with discharge, dimensions of channel, and the ordinary surface inclinations of rivers. The discharge corresponding to any intermediate channels or falls to those given in Tables XI. or XII., will be found with abundant accuracy, by inspection and simple interpolation; and in the same manner the channels from the discharges. Rivers have seldom greater falls than those given in TABLE XII., but in such an event we have only to divide the fall by 4, then twice the corresponding discharge will be that required. TABLE XIII. gives the comparative discharging powers of all similar channels, whether pipes or rivers, and the comparative dimensions from the discharges. We perceive from it, that an increase

of one-third in the dimensions doubles, and a decrease of one-fourth reduces the discharge to one-half. By means of this table, we can determine by a simple proportion, the dimensions of any given form of channel when the discharge is known. See Example 17, p. 30. See also the tables pp. 42, 43, 252 and 253.

The mean widths in Tables XI. and XII. are calculated for rectangular channels, and those having. side slopes of 13 to 1. Both these tables are, however, practically, equally applicable to any side slopes from 0 to 1 up to 2 to 1, or even higher, when the mean widths are taken and not those at top or bottom. A semihexagon of all trapezoidal channels of equal area has the greatest discharging power, and the semisquare and all rectangles exactly the same as channels of equal areas and depths with side slopes of 11 to 1. The maximum discharge is obtained between these for the semihexagon with side slopes, of nearly ½ to 1, but for equal areas and depths the discharge decreases afterwards as the slope flattens. The question of "HOW MUCH?" is here, however, a very important one; for, as we have already pointed out in equations (28) and (31), the differences for any practical purposes may be immaterial. This is particularly so in the case of channels with different side slopes, if, instead of the top or bottom, we make use of the mean width to calculate from. We then have only to subtract the ratio of the slope multiplied by the depth to find the bottom, and add it to find the top. If the mean width be 50 feet, the depth 5 feet, and the side slopes

2 to 1, we get $50 - (2 \times 5) = 40$ for the bottom, and $50 + (2 \times 5) = 60$ for the top width.

Side slopes of 2 to 1 present a greater difference from the mean slope of $1\frac{1}{3}$ to 1, than any others in general practice when new cuts are to be made. A triangular channel having slopes of 2 to 1, and bottom equal to zero, differs more in its discharging power from the half square, equal to it in depth and area, than if the bottom in each was equally increased, yet even here it is easy to show that this maximum difference is only 5½ per cent. bottom be increased so as to equal the depth, it is only 41 per cent.; when equal to twice the depth, 3.8 per cent.; and when equal to four times the depth, to 2 per cent.; while the differences in the dimensions taken in the same order are only 2.2, 1.8, 1.5, and 0.8 per cent. For greater bottoms in proportion to the depth the differences become of no comparative value. It therefore appears pretty evident, that TABLES XI. and XII. will be found equally applicable to all side slopes from 0 to 1 up to 2 to 1, by taking the mean widths. When new cuts are to be made, we see no reason whatever in starting from bottom rather than mean widths, to calculate the other dimensions; indeed, the necessary extra tables and calculations involved ought entirely to preclude us from doing so. Besides, the formulæ for finding the discharge vary in themselves, and for different velocities the coefficient of friction also varies.* Added to which

^{*} The coefficient m in the formula v = m $(rs)^{i}$ in rivers for velocities from 3 inches to 3 feet per second, varies from about 72 to 103; yet, strange to say, most tables are calculated from

the inequalities in every river channel, caused by bends and unequal regimen, preclude altogether any regularity in the working slopes and bottom, though the mean width would continue pretty uniform under all circumstances.

The quantities in TABLE XII. are calculated, from the velocities found from TABLE VIII., to correspond to a channel 70 feet wide and of different depths, the equivalents to which are given in TABLE XI. order to apply these tables generally to all open channels, the latter are to be reduced to rectangular ones of the same depth and mean width, or the reverse, as already pointed out. If the dimensions of the given channel be not within the limits of TABLE XI., divide the dimensions of the larger channels by 4, and multiply the corresponding discharge found in Table XII. by 32; for smaller channels, multiply the dimensions by 4, and divide by 32. In like manner, if the discharge be given and exceed any to be found in TABLE XIII., divide by 32, and multiply the dimensions of the suitable equivalent channel found in TABLE XI. by 4. If we wish to find equivalent channels of less widths than 10 feet for small discharges, multiply the discharge by 32, and divide the dimensions of the corresponding equivalent by 4. Many other multipliers and divisors as well as 4 and 32 may be found from TABLE XIII., such as 3 and

one coefficient alone; or, rather, from a formula equivalent to 94.17 (rs), which gives results suited only to a velocity of 16 inches. Dimensions of channels calculated by means of this formula are too small in one case, and too large in the other. In pipes the variation of the coefficients is shown in the small tables, pp. 214 and 217.

15.6, 6 and 88.2, 7 and 130, 9 and 243, 10 and 316, 12 and 499, &c. The differences indicated at pages 198 and 199, must be expected in the application of these rules, which will give, however, dimensions for new channels which can be depended on for doing duty.

It will be seen from Table XIII. that a very small increase in the dimensions increases the discharging power very considerably. Table XII. also shows that a small increase in the depth alone adds very much to the discharge. If we express in this latter case a small increase in the depth, d, by $\frac{d}{n}$, then it is easy to prove that the corresponding increase in the velocity, v, will be $\frac{v}{2n}$; and that in the

discharge D, $\frac{3D}{2n}$, if the surface inclination continue unchanged; but as it is always observable in rivers that the surface inclinations increase with floods, the differences in practice will be found greater than these expressions make it. As in a large river the surface inclination must be very small, four times the fall will add very little to the sectional area; yet this increase of fall will double the discharge, and we thence perceive how tributaries can be absorbed into the main channel without any great increase to its depth.

Mhere D, v, a b = bottom math of a channel a size elapse and in!:

are green, depth of mater = d = $\sqrt{\frac{D}{v} + \frac{b^2}{4}} - \frac{b}{2}$ Tor $\frac{D}{v} = (b + d)d$ a $d^2 + bd + \frac{b^2}{4} - \frac{D}{v} + \frac{b^2}{4}$ $d = \sqrt{\frac{D}{v} + \frac{b^2}{4}} - \frac{b}{2}$.

SECTION IX.

BEST FORMS OF THE CHANNEL.—REGIMEN.—VELOCITY.—
EQUALLY DISCHARGING CHANNELS.

We have seen above, that the determination of the hydraulic mean depth does not necessarily determine the section of the channel. If the form be a circle, the diameter is four times the mean radius; but, though this form be almost always adopted for pipes, the beds of rivers take almost every curvilineal and trapezoidal shape. Other things being the same, that form of a river channel, in which the area divided by the border is a maximum, is the best. This is a semicircle having the diameter for the surface line, and in the same manner, half the regular

figures, an octagon, hexagon, and square, in Fig. 33, are better forms for the channel, the areas and side slopes being constant, than any others of the same number of

sides. Of all rectangular channels, Diagram 4, in which ABCD is half a square, is the best cross section; and in Diagram 3, ACDB, half a hexagon, is the best trapezoidal form of cross section. When the width of the bottom, CD, Diagram 3, is given, and the slope

 $\frac{Aa}{Ca} = n$, then, in order that the discharge may be the greatest possible, we must have

$$c = \left\{ \frac{A}{2(n^2+1)!-n} \right\}^{\frac{1}{2}}$$
, and

$$CD = \frac{A}{CB} - n \times CB$$

$$= \{ [2 (n^2 + 1)^{\frac{1}{2}} - n] \times A \}^{\frac{1}{2}} - n \{ \frac{A}{2 (n^2 + 1)^{\frac{1}{2}} - n} \}^{\frac{1}{2}},$$

in which A is the given area of the channel. As, however, we have never known a river in which the slope of the natural banks continued uniform, even though made so for any improvements, we consider it almost unnecessary to give tables for different values of n. If, notwithstanding, we put ϕ for the inclination of the slope A c, equal angle C A a, we shall find,

as cot. $\phi = n$, and $\sqrt{n^2 + 1} = \frac{1}{\sin \theta}$, that the foregoing equations become

(120.)
$$c a = \left\{ \frac{A \sin \phi}{2 - \cos \phi} \right\}^{\frac{1}{2}} = \frac{CD}{2 \left\{ (n^2 + 1)^{\frac{1}{2}} - n \right\}};$$

and

(121.)
$$c D = \frac{A}{CB} - CB \times \cot \theta,^*$$

which will give the best dimensions for the channel when the angle of the slope for the banks is known.

When the discharge from a channel of a given area, with given side slopes, is a maximum, it is easy to show that THE HYDRAULIC MEAN DEPTH MUST BE HALF OF THE CENTRAL OR GREATEST DEPTH. This simple principle enables us to construct the best form of channel with great facility. Describe any circle on the drawing-board; draw the diameter and produce

^{*} When $c \, D = 0$. The channel is triangular; we get $A = c \, a^2 \times \cot \phi$, and $c \, a = \left(\frac{A}{\cot \phi}\right)^{\frac{1}{2}}$.

it on both sides, outside the circle; draw a tangent to the lower circumference parallel to this diameter, and draw the side slopes at the given inclinations, touching the circumference also on each side and terminating on the parallel lines: the trapezoid thus formed will be the best form of channel, and the width at the surface will be equal to the sum of the two side slopes. It is easy to perceive that this construction may be, simply, extended for finding the best form of a channel having any polygonal border whatever of more sides than three and of given inclinations.

Commencing with the best discharging form of channel, which in practice will have the mean width, about double the depth; an equally discharging section of double the width of the first will have the contents oneeleventh greater, and the depth less in the proportion of 1 to 1.85. A channel of double the mean width of the second must have the sectional area further increased by about one-fifth, and a further decrease in the depth from 1.67 to 1 nearly. The greater expense of the excavation at greater depths will, in general, more than counterbalance these differences in the contents of the channel. When the banks rise above the flood line, and are unequal in their section, the wider channel involves further upper extra cutting, but there is greater capacity to discharge extra and extraordinary flooding, the banks are less liable to slip or give way, the slopes may be less, and the velocity being also less, the regimen will, in general, be better preserved. The table of equally discharging channels, p. 252, will afford the means of calculating the difference of cubical contents.

Nore.—Half the top will give the length of the side slope. The top itself is the sum of the side slopes, and the border the sum of the top and bottom. The sum of the side slopes in any channel whatever is equal to the number corresponding to the slopes, is equal to the number of the slopes in the eighth column multiplied by the depth side area, or the slopes, is equal to the square of the depth multiplied by the depth added to this gives the area of the section. The top of the best form of channel should be at the level of the extraordinary flood line, and not at that of the mean annual surface.

When the sectional area is given, the above table shows that the semicircle is the best discharging channel, and the complete circle the worst; the latter is so, however, only compared with the open channels given in the table, it being the very best form for an enclosed channel flowing full. The best form of channel is particularly suited for new cuts in flat, marsh, callow, and fen lands, in which it is also often advisable to cut them with a level bed, up from the discharging point, in order to increase the hydraulic mean depth, and consequently the velocity and discharge.

As the quantity of water coming down a river channel in a season varies very considerably,-we have observed it in one case to vary from one to thirty, and occasionally in the same channel from one to seventy-five,—the proportion of the water section to the channel itself must also vary, and those relations of the depth, sides, and width to each other, above referred to, cease to hold good and be the best under such circumstances. If the object be to construct a mill-race, temporary drain for unwatering a river, or other small channel, in which the depth remains nearly constant, channels of the form of a half hexagon, diagram 3, Fig. 33, will be, perhaps, the best, if the tenacity of the banks permit the slope; but rivers, in which the quantity of water varies considerably, require wider channels in proportion to the depth; and also, that the velocity be so proportioned to the tenacity of the soil, or as it is termed "the regimen," that the banks and bed shall not vary from time to time to any injurious extent, and that any deposits made during their summer state, and during light freshes, shall be carried off periodically by floods. Another circumstance, also, modifies the effects of the water on the banks. It is this, that at curves, and turns, the current acts with greatest effect against the bank,

concave to the direction in which it is moving; deepening the channel there; undermining also the bank,

as at A, Fig. 34; and raising the bed towards the opposite side B. The reflexion of the current to the opposite bank from A acts also in a similar manner, lower down, upon it; and this natural operation proceeds, until the number of turns, increased length of channel, and loss of head from reflexion and unequal depths, bring the currents into regimen with the bed and banks. At all bends it is, therefore, prudent to widen the channel on the convex side B, Fig. 34, in order to reduce the velocity of approach; and if the bed be here also sunk below its natural inclination, as we see it in most rivers at bends, the velocity will be farther reduced, and the permanence of the bed better established.

The circumstances to be considered in deciding on the dimensions and fall of a new river course, after the depth to which the surface of the water is to be brought has been decided on, are the following:— The mean velocity must not be too slow, or aquatic plants will grow, and deposits take place, reducing the sectional area until a new and smaller channel is formed within the first with just sufficient velocity to keep itself clear. This velocity should not in general be less than from ten to fourteen inches per second. The velocity in a canal or river is increased very considerably by cutting or removing reeds and aquatic plants growing on the sides or bottom.*

The mean velocity must not be too quick, and should be so determined as to suit the tenacity and resistance of the channel, otherwise the bed and banks will change continually, unless artificially protected; it should not exceed

25 feet per minute in soft alluvial deposits.

40 , , clayey beds.

* "M. Girard a fait observer, avec raison, que les plantes aquatiques, qui croissent toujours sur le fond et sur les berges des canaux, augmentent considérablement le perimètre mouillé, et par suite la résistance; il a rapellé que Du Bûat, ayant mesuré la vitesse de l'eau dans le canal du Jard, avant et après la coupe des roseaux dont il était garni, avait trouvé un resultat bien moindre avant qu'après. En conséquence, il a presque doublé la pente donnée par le calcul . . "—Traité d'Hydraulique, p. 135. When the fall does not exceed a few inches per mile, the velocity, as determined from the inclination, is very uncertain, and for this reason it is always prudent to increase the depths and sectional areas of channels in flat lands, as far as the regimen will permit. In such cases the section of the channel should approximate towards the best form. See p. 238.

240 feet per minute in shingly.

300 ,, ,, shingly and rocky.

400 and upwards in rocky and shingly.*

A velocity of 180 feet per minute will remove angular stones the size of an egg. Mr. Phillips, under the Metropolitan Commissioners of Sewers, states that 2½ feet per second, or 150 feet per minute, is sufficient to prevent soil depositing in sewers.

The fall per mile should decrease as the hydraulic mean depth increases, and both be so proportioned that floods may have sufficient power to carry off the deposits, if any, periodically. The proportion of the width to the depth of the channel should not be derived, for new cuts or river courses, from any formula, but taken from such portions of the old channel as approximate in depth and in the inclination of the surface to that proposed. When the depth is nearly half the width, the formula shows, cateris paribus, that the discharge will be a maximum; but as (altogether apart from the question

of expense) the quantity of water discharged daily, at different seasons, may vary from one to seventy, or more, and "the regimen" has to be maintained, the best proportion between the width and depth of a new cut should be obtained, as we have stated, from some selected portion of the old channel, whose general circumstances and surface inclination approximate to those of the one proposed; and the side slopes of the banks must be such as are best suited to the soil. The resistance of the banks to the current being in general less than that of the beds, which get covered with gravel, and the necessary provision required for floods, appears to be the principal reason why rivers are in general so very much wider than about twice the depth, the relation which gives the minimum of friction.

The following table is given by Rennie, as an approximation, generally, to the actual state of rivers.* The surface inclinations, however, given in this table for the first and second classes, are very considerable for large rivers, and would give velocities which would effectually scour them. For a hydraulic mean depth of 12 feet, the velocity, with a fall of $\frac{1}{12000}$, would be 2 feet 8 inches per second by Du Buât's formula; and 3.3 feet per second by our formula. The description, therefore, can only apply to small channels. In fact, 4 inches to a mile, or $\frac{1}{15740}$, is a considerable inclination for a large river.

For enclosed channels, the circular form of sewer will have the largest scouring power, at a given hydraulic inclination. For the area of the sections being the same, the velocity in the circular channel will be a maximum. When the supply is intermittent, and the channel too large, the egg-shaped form

^{*} Report, for 1834, of the British Association.

with the smaller end for the bottom,—or the sides vertical with an inverted ridge-tile or V bottom for drains,—will have a hydrostatic flushing power to remove soil and obstructions, which a cylindrical channel, only partly full, does not possess; because a given quantity of water rises higher against the same obstruction, or obstacle, to the flow in the pipe. It must be confessed, however, that for small drains and house-sewage, this gain is immaterial, and is at best but effected by a sacrifice of space, material, and friction in the upper part of drains, from 6 to 12 inches in diameter. Besides this, the mere hydrostatic pressure is only intermittent, and during an ordinary, or heavy, fall of rain, the hydrodynamic power is always more efficient in scouring properlyproportioned cylindrical drains; and the workmanship in the form and joints is less imperfect than for more compound forms, as those with egg-shaped and inverted tile bottoms. The moulds and joints of cylindrical stone-ware drains, exceeding 12 inches in diameter, are seldom, however, in large quantities perfect; and the expense will exceed that of brick, stone, or other sufficient drains in most localities.

As to the increased discharging power which it is asserted by some, stone-ware cylindrical drains possess over other ordinary drains, no doubt it is true for small sizes, because the form, jointing, and surface are in general more smooth and circular; and for sewage matter,* the friction and adherence to the sides and bottom is less; any advantage from these causes becomes, however, immaterial for the larger

^{*} Weisbach found the coefficient of resistance 1.75 times as great for small wooden as for metallic pipes. All permeable pipes

sizes, as these can be constructed of brick or stone abundantly perfect to any form, and sufficiently smooth for all practical purposes, for in the larger properly-proportioned sizes the same amount of surface roughness opposed to the sewage matter is, comparatively, of no effect. The judicious inclination and form of the bottom, and properly curved junctions, are the principal points to be attended to. Smaller drains tile-bottomed, with brick or stone sides, and flat-covered, have one great advantage over circular pipes.* They can be opened up, for examination and repairs at any time with facility, and at the smallest expense; but greater certainty must be attached to the working of small stone-ware drains than to equally-sized small brick or stone drains, and they will be found, in general, also cheaper. This, however will depend on the locality.

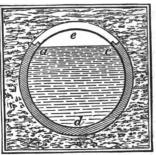

It may be observed in numerous experiments, that water flowing from a pipe does not entirely fill the orifice of exit, when the velocities are not considerable, and yet the results are found to be but slightly affected if a little more than three-fourths of the circumference be full. It is easy to demonstrate that the full circle does not give the maximum discharging velocity as has been generally believed, but

present greater resistance than impermeable ones; hence the principal advantage derived from glazing.

* Half-socket joints at bottom would remedy this imperfection in small pipes, and they could be better laid and cemented. A semicircular flange laid on at top would effectually protect the joint on the upper side. Latterly Doulton has cut off an upper segment from the pipe, which can be removed for cleaning. And it may be demonstrated, that when this is a segment of 78½ degrees, the lower portion will discharge more than a full pipe at the same inclination.

when filled to the height of the chord ac of arc aec of $78\frac{1}{2}$ degrees, and where the velocity is $9\frac{1}{2}$ per cent. over that due to the full circle, for then the $\frac{area}{arc} \frac{adc}{ade}$ is a maximal of the full circle.

Fig. 34a.

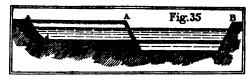

mum, and the length of

the arc adc is equal to the tangent of the supplemental arc aec, as may be without difficulty demon-The hydraulic mean depths of the circle and larger segment are to each other as 5 to 6, and their square roots, which are as the velocities or scouring powers, are as 1 to 1.095. The discharging powers are to each other as 1×3.1416 to 1.095 $\times 2.946$, or as 1 to 1.026, which shews that the segment adc has also a greater discharging power than the whole circle of nearly three per cent. These facts, which were first pointed out by the author, are not unimportant in matters connected with pipe-drains and sewerage. The effects of greater velocity and discharge here pointed out, are sometimes increased, in short pipes, from the fall between the surface a c, and the surface from which the head is measured, being greater than the fall to the top of the pipe at e, or from the inclination of the surface of the water in the pipe being greater than the inclination of the pipe itself.

EQUALLY DISCHARGING CHANNELS.

In order that different channels should have the same discharging power, the inclination of the surface being the same, the areas must be inversely as the square roots of the hydraulic mean depths. The channel a d c B, Fig. 35, will have the same discharge as the channel ADCB if they be to each other

as
$$\left\{\frac{ADCB}{AD+DC+CB}\right\}^{\frac{1}{2}}$$
 to $\left\{\frac{adcB}{ad+dc+cB}\right\}^{\frac{1}{2}}$,

and hence the square root of the cube of the channel area, divided by the border, must be constant. With a fall of one or more feet to a mile, two channels, one 70 feet wide and 1 foot deep, and the other 20 feet wide and $2\frac{1}{2}$ feet deep, will have the same discharge. If we put w for the width and d for the depth of any rectangular channel, then

$$\left\{\frac{w^3 d^3}{w+2 d}\right\}^{\frac{1}{2}} = m; \text{ we therefore have the cubic equation}$$

$$(122.) \qquad \qquad d^3 - \frac{2 m^2}{v^3} d = \frac{m^2}{v^2}$$

for finding the depth d of any other rectangular channel whose width is w, of the same discharging power. We have calculated the depths d for different widths of channel from this equation, assuming a width of 70 feet and different depths to find m from. The results are given in TABLE XI., which will be found sufficiently accurate for all practical purposes, when the banks are sloped, by taking the mean width. This table is equally applicable to any measures whatever, to their multiples, and sub-multiples.

If the hydraulic inclinations vary, then the \sqrt{rs} must be inversely as the areas of the channels when $\sqrt{rs} \times$ channel or the discharge is constant; and if

the area of the channel and discharge be each constant, r must vary inversely as s; and r s be also constant. For instance, a channel which has a fall of four feet per mile, and a hydraulic mean depth of one foot, will have the same discharge as another channel of equal area, having a hydraulic mean depth of four feet, and a fall per mile of only one foot. If in Table XII. we take the same discharge from the columns for different inclinations, we shall get the mean rectangular dimensions corresponding to them in the first column, and thereby be enabled to select an equally discharging channel from Table XI., suited to an increase or decrease of the hydraulic inclination.*

We have, however, calculated for this edition the table at p. 252, of equally discharging river channels, with a primary channel having a mean width of 100, instead of 70, as in Table XI.; and in the table at p. 253 we have given the discharges at different inclinations from this new primary channel, to find those from its equivalents. The tables at pp. 42, 43, 253, and Table VIII., have been calculated from Du Buât's formula. For slow velocity of only a few inches per second, the dimensions should be increased by about one-sixth, and the discharges by about one-half.

With reference to pipes, it is apparent that a given depth of roughness or contraction arising from any

^{*} Tables similar to numbers XI., XII., and XIII., but on a much more extended scale, have been printed and published by Mr. Weale, on a separate sheet for office use, and may be had from him.

cause will have a greater effect the smaller the diameter becomes. Now in practice, it is necessary to increase the diameter beyond what is found by calculation. For small service pipes half-an-inch is the smallest diameter in general use. For mains and sub-mains the value of c_t in equation (74B), or at p. 214, should at least be doubled, or the discharge taken at one and a half times its amount to find the diameter. By enlarging the diameter by one-seventh, one: half the amount will be added to the discharge, very nearly; and by increasing the diameter by one-third, the discharge will be doubled. In a broad and practical sense, and considering the losses arising from depositions,* pipes under two inches should have onethird or more added to their calculated dimensions. and larger pipes from one-third to one-seventh-even after making allowance for junctions, bends, and contractions. For large conduits or channels the allowance need not be so large, if the maximum quantity to be conveyed be duly estimated.

* Mr. Bateman lately in giving evidence says :-- "He wished to mention a circumstance which might be useful with regard to the spongillæ found in the Dublin water pipes. At Manchester, before the introduction of soft water, the city was supplied with hard water, which favoured the growth of a small fresh-water mussel, which thickly line the reservoirs and pipes. There were myriads of them, and they lay in the pipes as thick as paving These were caused by the large quantity of lime in the water. He was curious to see what would be the effect of passing water without lime. This was done ten or eleven years ago, and the result was that these mussels had entirely disappeared. There was no longer anything from which they could make their shells. and for years, on their discharge, the small pipes were found choked with them. If soft water were supplied to Dublin in place of the present hard water, which probably tavoured the growth of spongillæ, they would probably disappear."

SECTION X.

EFFECIS OF ENLARGEMENTS AND CONTRACTIONS.—BACKWATER
WEIR CASE.—LONG AND SHORT WEIRS.

When the flowing section in pipes or rivers expands or contracts suddenly, a loss of head always ensues; this is probably expended in forming eddies at the sides, or in giving the water its new section. A side current, moving slowly upwards, may be frequently observed in the wide parts of rivers, when the channel is unequal, though the downward current, at the centre, be pretty rapid; and though we may assume generally that the velocities are inversely as the sections, when the channels are uniform, we cannot properly do so when they are not, and the motions so uncertain as those referred to. When a pipe is

contracted by a diaphragm at the orifice of entry, Fig. 27, we have seen (equation 60), that the loss of head is,

(123.)
$$h = \frac{\left(1 - \frac{A^2}{C^2}\right)v^2 + \left(\frac{A}{a c_d} - 1\right)^2 v^2}{2 q}.$$

When the diaphragm is placed in a uniform pipe, Fig. 36, then $\Delta = c$, and we get the loss of head

(124.)
$$h = \frac{\left(\frac{A}{a c_d} - 1\right)^2 v^2}{2 a},$$

and the coefficient of resistance

$$(125.) c_r = \left(\frac{\Lambda}{a c_A} - 1\right)^2,$$

as in equation (67). The coefficient of discharge c_4 is

here equal to the coefficient of contraction c_a , or very nearly. Now we have shown in equation (45), and the remarks following it, that the value of the coefficient of discharge, c_d , varies according to the ratio of the sections, $\frac{A}{a}$,* and in Table V. we have calculated the new coefficients for different values of the ratios, and different values of the primary coefficient c_d . If we assume c_d , when A is very large compared with a, to be 628, we then find by attending to the remarks at pp. 109 and 128, that the different values of c_d corresponding to $807 \times \frac{A}{a}$, taken from Table V., are those in columns Nos. 2 and 5 of the next small

TABLE OF COEFFICIENTS FOR CONTRACTION, BY A DIAPHRAGM IN A PIPE,

* The general value of c_e , as given by Professor Rankine, is $c_e = \frac{\cdot 618}{\left(1 - \cdot 618 \frac{a^2}{A^2}\right)^{\frac{1}{2}}}$, which is equal to unity when a = A, as it

should be; and equal to \cdot 618, when a is very small, compared with a, as it also should be when the diaphragm is a thin plate, but not otherwise. If the thickness of the diaphragm be twice the diameter of the orifice a, the coefficient of discharge would be \cdot 815; and if the higher arris be rounded, this would be increased to 1, in which cases the expression would clearly fail; the thickness of the diaphragm and the form of the aperture a must also be considered.

table, the values of the coefficient of resistance, in columns 3 and 6, being calculated from equation (125) for the respective new values of the coefficient of discharge thus found. The table shows that when the aperture in a diaphragm is $\frac{2}{10}$ ths of the section of the pipe, that 47 times the head due to the velocity is lost thereby. If the aperture in the diaphragm be rounded at the arrises, the loss will not be so great, as the primary coefficient c_d will then be greater than that due to an orifice in a thin plate: see coefficients, p. 174.

When there are a number of diaphragms in a tube, the loss of head for each must be found separately, and all added together for the total loss. If the diaphragms, however, approach each other, so that the water issuing from one of the orifices a, Fig. 36, shall pass into the next before it again takes the velocity due to the diameter of the pipe, the loss will not be so great as when the distance is sufficient to allow this change to take place. This view is fully borne out by the experiments of Eytelwein with tubes 1.03 inch in diameter, having apertures in the diaphragms of .51 inch in diameter.

Venturi's twenty-fourth experiment, with tubes varying from '75 inch to '934 inch in diameter at the junction with the cistern, so as to take the form of the contracted vein, and expanding and contracting along the length from '75 to 2 inches and from 2 inches to '75 inch alternately, shows the great loss of head sustained by successive enlargements and contractions of a channel, even when the junction of the parts is gradual. Calling the coefficient for the short

tube, with a junction of nearly the form of the contracted vein, 1, then the following coefficients are derivable from the experiment:—

Short tube with round	led	jw	acti	ion			•		1.

the five enlarged pa	ırts						,		·736

The head, in the experiment, was 32½ inches. Venturi states that no observable differences occurred in the times of discharge when the enlarged portions were lengthened from 3½ to 6½ inches. See tables, pp. 152 and 191.

With reference to this experiment, so often quoted, it is necessary to remark that the diameters of the enlarged portions were 2 inches each, while the lengths varied only from 3½ to 6½ inches, and consequently were at most only 3½ times the diameter. Now with

such a large ratio of the width to the length of the enlarged portions, a A B b, Fig. 37, it is pretty clear that a good deal of the head

is lost by the impact of the moving water on the shoulders A and B. That this is so is evident from the fact, stated by the experimenter, of the time of discharge remaining the same when a A, in five different enlargements, was increased from $3\frac{1}{8}$ to $6\frac{1}{8}$ inches; though this must have lengthened the whole

tube from 36 to 50 inches,* thereby increasing the loss from friction proportionately, but which happened to be compensated for by the reduction in the resistances from impact at A and B, and in the eddies, by doubling the lengths from a to A.

If, however, the length from a to a be very large compared with the diameter, and the junctions at a, a, b, and b, be well grafted, less loss will arise from the enlargement than if the smaller diameter continued all along uniform. The explanation is clear, as the resistance from friction is inversely as the square roots of the mean radii; and the length being the same, the loss must be less with a large than a small diameter.

These remarks, mutatis mutandis, apply equally to rivers as to pipes. We have already, pp. 140 and 147, pointed out the effects of submerged weirs and contracted river channels, and given formulæ for calculating them.

BACKWATER FROM CONTRACTIONS IN RIVERS.

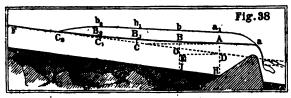

A river may be contracted in width or depth, by jetties or by weirs; and when the quantity to be discharged is known, we have given, in formulæ (9), (55), and (57), equations from which the increase of head may be determined. The effect of a weir, jetty, or contracted channel of any kind, is to increase the depth of water above; and this is sometimes necessary for navigation purposes, or to obtain a head for mill power. When a weir is to rise over the surface, we can easily find, from the discharge and length, the discharge per minute over each foot of length, with which, and the coefficient due to the ratio of the

Digitized by Google

^{*} The dimensions throughout this experiment are given as in the original, viz. in French inches.

sections, on and above the weir, found from Table V., we can find the head from Table VI. For submerged weirs and contracted widths of channel, the head can be best calculated, by approximation, from the equations above referred to.

The head once determined, the extent of the backwater is a question of some importance. If $\mathbf{r} \cdot \mathbf{c} \cdot \mathbf{o} \cdot \mathbf{d}$, Fig. 38, be the original surface of a river, and $\mathbf{a} \cdot \mathbf{a} \cdot \mathbf{b} \cdot \mathbf{r}$ the raised surface by backwater from the weir at \mathbf{a} , then the extent $\mathbf{a} \cdot \mathbf{r}$ of this backwater, in a regular channel, will be from 1.5 to 1.9 times $\mathbf{a} \cdot \mathbf{c} \cdot \mathbf{d}$ drawn parallel to the horizon to meet the original surface in \mathbf{c} . This rule

will be found useful for practical purposes; but in order to determine more accurately the rise for a given length, B₁ B₂ or B₁ B, of the channel, it is necessary to commence at the weir and calculate the heights from A to B, B to B₁, and from B₁ to B₂ separately, the distance from A to B₂ being supposed divided into some convenient number of equal parts, so that the lengths A B, B B₁, &c., may be considered free from curvature. Now, as the head A D is known, or may be calculated by some of the preceding formulæ, the section of the channel at the head of the weir also becomes known, and thence the mean velocity in it, by means of the discharge over the weir. Putting A for the area of the channel at A H, d for its depth A H, and v for the mean velocity; also A₁ for

the area of the channel at BI, d_1 for its depth, and v_1 for its mean velocity; b_m the mean border between the sections at AH and BI; r_m the mean hydraulic depth; $\frac{v+v_1}{2}$ the mean velocity; AD = h; $BO = h_1$; the sine of angle ODE = s; and the length AB = DO nearly = l; we get $A \times v = A_1 \times v_1$ and $r_m = \frac{A + A_1}{2b_m}$; but as, in passing from B to A, the velocity changes from v_1 to v, there is a loss of head equal $\frac{v_1^2 - v^2}{2g}$, and if c_i be the coefficient of friction, there is a loss of head from this cause equal $c_i \times \frac{l}{r_m} \times \frac{\left(v_1 + v\right)^2}{2g}$;

hence the whole change of head in passing from B to A is equal to $c_i \times \frac{l}{r_m} \times \frac{(v_1 + v)^3}{8g} - \frac{v_1^2 - v^2}{2g}$. But this change of head is equal to BE — AD = BO + OE — AD = $h_1 + ls - h$, whence we get

(126.)
$$h_{1}-h=d_{1}-d=c_{t}\times\frac{l}{r_{m}}\times\frac{(v_{1}+v)^{2}}{8g}$$
$$-\frac{v_{1}^{2}-v^{2}}{2g}-ls;$$

or as $v_1 = \frac{A}{A_1}$, and $r_m = \frac{A}{2} + \frac{A_1}{b_m}$, we get, by a few reductions and change of signs,

(127.)
$$h - h_1 = \left(s - c_t \times b_m \times \frac{A + A_1}{2 A_1^2} \times \frac{v^3}{2 g}\right) l + \frac{A^2 - A_1^2}{A^2} \times \frac{v^3}{2 g};$$

and therefore we get

(128.)
$$l = \frac{h - h_1 - \frac{A^2 - A_1^2}{A_1^3} \times \frac{v^2}{2g}}{s - c_t \times \frac{b_m \times (A + A_1)}{2A_1^2} \times \frac{v^2}{2g}},$$

from which we can calculate the length l corresponding to any assumed change of level between A and B. Then, by a simple proportion we can find the change of level for any smaller length. To find the change of level directly from a given length does not admit of a direct solution, for the value of $h - h_1$ in equation (127) involves A_1 , which depends again on $h - h_1$, and further reduction leads to an equation of a higher order; but the length corresponding to a given rise, h_1 , is found directly by equation (128).

When the width of the channel, w, is constant, and the section equal to $w \times d$ nearly, the above equations admit of a further reduction for $A_1 = d_1 w$ and A = dw; by substituting these values in equation (127) it becomes, after a few reductions,

$$(129.) \quad h - h_1 = d - d_1$$

$$= \left(s - c_t \times b_m \times \frac{d \times d_1}{2 \ d \ w} \times \frac{v^2}{2 \ g}\right) l + \frac{d^3 - d_1^2}{d_1^3} \times \frac{v^2}{2 \ g};$$

or, as it may be further reduced,

(130.)
$$h-h_1 = \frac{s-c_t \times \frac{b_m}{d_1 w} \times \frac{d+d_1}{2 d_1} \times \frac{v^2}{2 g}}{1-\frac{d+d_1}{d_1^2} \times \frac{v^2}{2 g}} \times l.$$

Now, we may take in this equation for all practical purposes,

$$\frac{d+d_1}{2d_1} \times \frac{b_m}{d_1w} = \frac{b}{dw},$$

approximately, b being the border of the section at

AH; and also, $\frac{d+d_1}{d_1^2} = \frac{2}{d}$, approximately; therefore we shall have

(131.)
$$h-h_1=\frac{s-c_i\times\frac{b}{d\,w}\times\frac{v^s}{2\,g}}{1-\frac{2}{d}\times\frac{v^s}{2\,g}}\times l;$$

and

(132.)
$$l = \frac{(h-h_1) \times \left(1 - \frac{2}{d} \times \frac{v^2}{2g}\right)}{s - c_i \times \frac{b}{dw} \times \frac{v^2}{2g}}.$$

Now, as $\frac{b}{dw} = \frac{1}{r}$, 2g = 64.4, and the mean value of the coefficient of friction for small velocities $c_i = .0078$, we shall get

(133.)
$$h_1 = h - \frac{64 \cdot 4 ds - 0078 \frac{d}{r} v^2}{64 \cdot 4 d - 2 v^2} \times l;$$

and

(134.)
$$l = \frac{(h - h_1) \times (64 \cdot 4 d - 2 v^3)}{64 \cdot 4 d s - 0078 \frac{d}{r} v^3},$$

very nearly. Having by means of these equations found AB from BO or BE, and BO from AB, we can in the same manner proceed up the channel and calculate B_1 C, B_2 C₁, &c., until the points B, B_1 , B_2 in the curve of the backwater shall have been determined, and until the last nearly coincides with the original surface of the river. When $h_1 = 0$, we shall have

$$h = \frac{64 \cdot 4 \ d \ s - \cdot 0078 \frac{d}{r} v^{2}}{64 \cdot 4 \ d - 2 \ v^{2}} \times l.$$

If we examine equation (134) it appears that when $64 \cdot 4 d = 2 v^2$, l must be equal to zero; or when $\frac{d}{2} = \frac{v^2}{64 \cdot 4}$, equal the height due to the velocity v. When l is infinite, $64 \cdot 4 d$ must exceed $2 v^2$, and $64 \cdot 4 ds$ equal to $0078 \frac{d}{r} v^3$;

or,
$$\frac{64.4 \, rs}{.0078} = v^3$$
, and $v = 90.9 \, \sqrt{rs}$.

This is the velocity due to friction in a channel of the depth d, hydraulic mean depth r, and inclination s; and, as in wide rivers r = d nearly, v = 90.9 \sqrt{ds} , but when the numerator was zero we had from it $v = \sqrt{32.2} d$; equating these values of v, we get $s = 0039 = \frac{1}{256}$ nearly: see p. 139. Now, the larger the fraction s is, the larger will the velocity v become; and the larger v becomes, the more nearly, in all practical cases, will the terms

$$64.4 d - 2 v^{2}$$
 and $64.4 d s - .0078 \frac{d}{r} v^{2}$,

in the numerator and denominator of equation (134), approach zero; when $64\cdot 4 d - 2v^2$ becomes zero first, l = 0; when $64\cdot 4 ds = \cdot 0078 \frac{d}{r}v^2$ becomes zero first, l equals infinity; and when they both become zero at the same time, $l = h - h_1$, and $s = \frac{1}{256}$, see p. 139; if s be larger than this fraction, the numerator in equation (134) will generally become zero before the denominator, or negative, in which cases l will also be zero, or negative; and the backwater will take the

form \mathbf{r} \mathbf{c}_2 b_2 b_1 b a_1 a, Fig. 38, with a hollow at \mathbf{c}_2 . Bidone first observed a hollow, as \mathbf{r} \mathbf{c}_2 b_2 , when the inclination s was $\frac{1}{s_0}$. When the inclination of a river channel changes from greater to less, the velocity is obstructed, and a hollow similar to \mathbf{r} \mathbf{c}_2 b_2 sometimes occurs; when the difference of velocity is considerable, the upper water at b_2 falls backwards towards \mathbf{c}_2 and \mathbf{r}_3 , and forms a bore, a splendid instance of which is the pororoca, on the Amazon, which takes place where the inclination of the surface changes from 6 inches to $\frac{1}{s}$ th of an inch per mile, and the velocity from about 22 feet to $\frac{1}{2}$ feet per second.

WEIR CASE, LONG AND SHORT WEIRS.

When a channel is of very unequal widths, above a weir, we have found the following simple method of calculating the backwater sufficiently accurate, and the results to agree with observation. Having ascertained the surface fall due to friction in the channel at a uniform mean section, add to this fall the height which the whole quantity of water flowing down would rise on a weir having its crest on the same level as the lower weir, and of the same length as the width of the channel in the contracted pass. The sum will be the head of water at some distance above such pass very. nearly. A weir was recently constructed on the river Blackwater, at the bounds of the counties Armagh and Tyrone, half a mile below certain mills, which, it was asserted, were injuriously affected by backwater thrown into the wheel-pits. The crest of the weir, 220 feet long, was 2 feet 6 inches below the

pit; the river channel between varied from 50 and 57 feet to 123 feet in width, from 1 foot to 14 feet deep; and the fall of the surface, with 3 inches of water passing over the weir and the sluices down; was nearly 4 inches in the length of half a mile. Having seen the river in this state in summer, the writer had to calculate the backwater produced by different depths passing over the weir in autumn and winter, which in some cases of extraordinary floods were known to rise to 3 feet. The width of the channel about 60 feet above the weir averaged 120 The width, 2050 feet above the weir and 550 feet below the mills, was narrowed by a slip in an adjacent canal bank, to 45 feet at the level of the top of the weir, the average width at this place as the water rose being 55 feet. The channel above and below the slip widened to 80 and 123 feet. Between the mills and the weir there were, therefore, two passes; one at the slip, averaging 55 feet wide; another above the weir, about 120 feet wide. Assuming as above; that the water rises to the heights due to weirs 55 and 120 feet long, at these passes, we get, by an easy calculation, or by means of TABLE X., the heads in columns two and four of the following table, corresponding to the assumed ones on the weir, given in the first column.

As the length of the river was short, and the hydraulic mean depth pretty large, the fall due to friction for 60 feet above the weir was very small, and therefore no allowance was made for it; even the distance to the slip was comparatively short, being less than half a mile, and as the water approached it

with considerable velocity, this was conceived, as the observations afterwards showed, to be a sufficient compensation for the loss of head below by friction. The observations were made by a separate party, over whom the writer had no control, and it is necessary to remark, that with the same head of water on the weir, they often differed more from each other than from the calculation. This, probably, arose from the different directions of the wind, and the water rising during one observation, and falling during another.

The true principle for determining the head at g, Fig. 39, apart from that due to friction, is that pointed out at pages 142 and 147; but when the passes are very near each other, or the depth d_2 , Fig. 23, is small, the effect of the discharge through d_2 is inconsiderable in reducing the head, as the contraction and loss of vis-viva are then large, and the head d_1 becomes that due to a weir of the width of the contracted channel at A, nearly. The reduction in the extent of the backwater, by lowering the head on a longer weir, is found by taking the difference of the amplitudes due to the heads at q, Fig. 39, in both cases, as determined from equations (56), (128), et seq. This will seldom exceed a mile up the river, as the surface inclination is found to be considerably greater than that due to mere friction and velocity, and hence the general failure of drainage works designed on the assumption that the lowering of the head below, by means of long weirs, extends its effects all the way up a channel. We must nearly treble the length of a weir before the head passing over can be reduced by one-half, Table X., even supposing the circumstances of approach to be the same: surely several engineering appliances for shorter weirs, during periods of flood, would be found more effective and far less expensive than this alternative, with its extra sinking and weir basin for drainage purposes.

The advocates for the necessity of weirs longer than the width of the channel, for drainage purposes, must show that the reduction of the head and extent of backwater above g, Fig. 39, is not small, and that the effects extend the whole way up the channel,

or at least as far as the district to be benefited. Practice has heretofore shown, that long weirs have failed (unless after the introduction of sluices or other appliances) in producing the expected arterial drainage results, notwithstanding the increased leakage from increased length, which must accompany their construction.

The deepening in the weir basin abera is mostly of use in reducing the surface inclination between a b and A B by increasing the hydraulic mean depth; but, thereby, the velocity of approach is lessened, and therefore the head at r increased. When the length of a weir basin $a ext{ E}$ exceeds that point where these two opposite effects balance each other, there will be a gain by the difference of the surface inclinations in favor of the long weir: but unless a E exceeds half a mile, this difference cannot amount to more than 3 or 4 inches, unless the river be very small indeed; and if the channel be sunk for the long weirs B A or b a, it should also be sunk to at least the same depth and extent for the short weirs B e, b a, otherwise there is no fair comparison of their separate merits. The effect of the widening between a b and AB, the depth being the same, is also to reduce the

surface inclination from a to E; but, as before, unless a E be of considerable length, this gain will also be small. Now A E, at best, is but a weir the direct width of the new channel at A E, and if the length a E be considerable, we have an entirely new river channel with a direct weir at the lower end, and the saving of head effected arises entirely from the larger channel, with a *direct* transverse weir at the lower end.

By referring to TABLE VIII., it will be found that for a hydraulic mean depth of 5 feet a fall of 71 inches per mile will give a velocity of 2 feet per second; if we double the depth, a fall of 4 inches will give the same velocity; and for a depth of only 2 feet 6 inches, a fall of 12½ inches is necessary, This is a velocity much larger than we have ever observed in a weir basin, yet we easily perceive that the difference in the inclinations for a short distance, \mathbf{E} a of a few hundred feet, must be small. If one section be double the other, the hydraulic mean depth remaining constant, the velocity must be one-half, and the fall per mile one-fourth, nearly, This would leave $7\frac{1}{4} - 2 = 5\frac{1}{4}$ inches per mile, or 1 inch per 1000 feet nearly, as the gain with a hydraulic mean depth of 5 feet for a double water channel. For greater depths the gain would be less, and the contrary for lesser depths.

Is the saving of head and amplitude of backwater we have calculated worth the increased cost of long weirs and the consequent necessity and expense of sinking and widening the channels for such long distances? We think not; indeed, the sinking in the basin immediately at the weir is absolutely injurious,

by destroying the velocity of approach, and increasing the contraction. The gradual approach of the bottom towards the crest, shown by the upper dotted line $b \to \infty$ in the section, Fig. 39, and a sudden overfall, will be found more effective in reducing the head, unless so far as leakage takes place, than any depth of sinking for nearly 80 or 100 feet above long weirs.

In most instances, the extra head will be only perceived by an increased surface inclination, which may extend for a mile or more up the channel, according to the sinking and widening.

It is a general rule that, for shorter weirs, the coefficients of discharge decrease; this arises from the greater amount of lateral contraction, and is more marked in notches or Poncelet weirs, than for weirs extending from side to side of the channel; but for weirs exceeding 10 feet in length the decrease in the coefficients from this cause is immaterial, unless the head passing over bear a large ratio to the length; and we even see from the coefficients, page 80, derived from Mr. Blackwell's experiments, that with 10 inches head passing over a 2-inch plank, the coefficient for a length of 3 feet is .614; for a length of 6 feet .539; and for a length of 10 feet .534; showing a decrease as the weir lengthens, but which may, in the particular cases, be accounted for. We have before referred to other circumstances which modify the coefficients, yet we may assume generally, without any error of practical value, that the coefficients are the same for different weirs extending from side to side of a river. If, then, we put w and w_1 for the lengths of two such weirs, we shall have the relation

of the heads d and d_1 for the same quantity of water passing over, as in the following proportion:—

$$d:d_1::w_1^{\frac{2}{3}}:w_1^{\frac{2}{3}}$$
;

and therefore

(135.)
$$d_1 = \left(\frac{w}{w_1}\right)^{\frac{3}{3}} \times d$$

By means of this equation we have calculated TABLE X., the ratio $\frac{w}{w_1}$ being given in columns 1, 3,

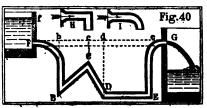

5 and 7, and the value of $\binom{w}{w_1}^{\frac{1}{3}}$, or the coefficient by which d is to be multiplied, to find d_1 in columns 2, 4, 6 and 8. It appears also, that if we take the heads passing over any weir in a river in an arithmetical progression, the heads then passing over any other weir in the same river must also be in arithmetical progression, unless the quantity flowing down varies from erogation or supply, such as drawing off by millraces, &c. If c_4 be the coefficient for a direct weir, $94 c_4$ will answer for an obliquity of 45° , and $91 c_4$ for an angle of 65° .

SECTION XI.

BENDS AND CURVES.—BRANCH PIPES.—DIFFERENT LOSSES OF HEAD.—GENERAL EQUATION FOR FINDING THE VELOCITY.—
HYDROSTATIC AND HYDRAULIC PRESSURE.—PIEZOMETER.—
CATCHMENT BASINS.—RAIN-FALL PER ANNUM.

The resistance or loss of head due to bends and curves has now to be considered. If we fix a bent pipe, FBCDEG, Fig. 40, between two cisterns, so as

to be capable of revolving round in collars at r and G, we shall find the time the water takes to sink a given distance from f

to r in the upper cistern the same, whether the tube occupy the position shown in the figure or the horizontal position shown by the dotted line rbcdec. This shows that the resistances due to friction and to bends are independent of the pressure. If the tube were straight, the discharge would depend on the length, diameter, and difference of level between f and c, and may be determined from the mean velocity of discharge, found from Table VIII. or equation (79). Here, however, we have to take into consideration the loss sustained at the bends and curves, and our illustration shows that it is unaffected by the pressure.

The experiments of Bossut, Du Buât, and others, show that the loss of head from bends and curves—like that from friction—increases as the square of the velocity; but when the curves have large radii, and the bends are very obtuse, the loss is very small. With a head of nearly 3 feet, Venturi's twenty-third experiment, when reduced, gives—for a short straight tube 15 inches long, and 1½ inch in diameter, having the junction of the form of the contracted vein, very nearly .873 for the coefficient of discharge. When of the same length and diameter, but bent as in Diagram I, Fig. 40, the coefficient is reduced to .785; and when bent at a right angle as at H, Fig. 40, the co-

efficient is further reduced to .560. In these respective cases we have therefore*

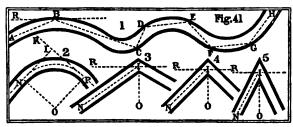

1.
$$v = .873 \sqrt{2g h}$$
, and $h = 1.312 \times \frac{v^2}{2g}$;

2.
$$v = .785 \sqrt{2gh}$$
, and $h = 1.623 \times \frac{v^2}{2g}$;

3.
$$v = .560 \sqrt{2gh}$$
, and $h = 3.188 \times \frac{v^3}{2g}$;

showing that the loss of head in the tube H, Fig. 40, from the bend, is $1.876 \times \frac{v^2}{2g}$, or nearly double the theoretical head due to the velocity in the tube. The loss of head by the circular bend is only $311\frac{v^2}{2g}$, or not quite one-sixth of the other.

Du Buât deduced, from about twenty-five experiments, that the head due to the resistance in any bent tube ABCDEFGH, diagram 1, Fig. 41, depends

on the number of deflections between the entrance at A and the departure at H; that it increases at each

• It is stated that the time necessary for the discharge of a given quantity of water through a straight pipe being 1, the time for an equal quantity through a curve of 90° would be 1·11, with a right angle 1·57; two right angles would increase the time to 2·464, and two curved junctions to only 1·23. Vide Report on the Supply of Water to the Metropolis, p. 237, Appendix No. 8.

reflection as the square of the sine of the deflected angle, ABR for instance, and as the square of the velocity; and that if ϕ , ϕ_1 , ϕ_2 , ϕ_3 , &c., be the number of degrees in the angles of deflection at B, C, D, E, &c., then for measures in French inches the height h_b , due to the resistances from curves, is

(136.)
$$h_b = \frac{v^3(\sin^2\phi + \sin^2\phi_1 + \sin^2\phi_2 + \sin^2\phi_3 + \&c.)}{3000}$$

which for measures in English inches becomes

(137.)
$$h_b = \frac{v^3(\sin^3\phi + \sin^3\phi_1 + \sin^2\phi_2 + \sin^3\phi_3 + &c.)}{3197}$$

and for measures in English feet,

(138.)
$$h_b = \frac{v^2(\sin^2\phi + \sin^2\phi_1 + \sin^2\phi_2 + \sin^2\phi_3 + \sec^2\phi_4)}{266\cdot4}$$

or, as it may be more generally expressed for all measures,

(139.)
$$h_b = (\sin^2 \phi + \sin^2 \phi_1 + \sin^2 \phi_2 + \sin^2 \phi_3 + \&c.) \times \frac{v^2}{8 \cdot 27 g}$$
, in which $\frac{v^2}{8 \cdot 27 g} = \frac{v^2}{266 \cdot 4} = \cdot 00375 \ v^2$ in feet.

The angle of deflection, in the experiments from which equation (136) was derived, did not exceed 36°. We have already shown the loss of head from the circular bend in diagram I. Fig. 40, where the angle of deflection is nearly 45°, to be $311 \frac{v^2}{2g} = 00483 v^2$, but as the sin. $45^\circ = 707$; $\sin^2 45^\circ = 5$ we get $00483 v^2 = 00966 v^2 \times \sin^2 45^\circ$, or more than two and a half times as much as Du Buât's formula would give; and if we compare it with Rennie's experiments,* with a pipe 15 feet long, $\frac{1}{2}$ inch diameter, bent into fifteen curves, each $\frac{3}{2}$ inches radius,

^{*} Philosophical Transactions for 1831, p. 488.

we should find the formula gives a loss of head not much more than one half of that which may be derived from the observed change, 419 to 370 cubic feet per minute in the discharge. See p. 278.

Dr. Young* first perceived the necessity of taking into consideration the length of the curve and the radius of curvature. In the twenty-five experiments made by Du Buât, he rejected ten in framing his formula, and the remaining fifteen agreed with it very closely. Dr. Young finds

(140.)
$$h_b = \frac{.0000045 \phi \rho^{\frac{1}{2}} \times v^2}{\rho};$$

where ϕ is the number of degrees in the curve N P, diagram 2, Fig. 41, equal the angle N O P; $\rho = 0$ N the radius of curvature of the axis; h_b the head due to the resistance of the curve, and v the velocity, all expressed in French inches. This formula reduced for measures in English inches is

(141.)
$$h_b = \frac{0000044 \phi \rho^{\dagger} \times v^2}{\rho};$$

and for measures in English feet,

(142.)
$$h_{b} = \frac{.000006 \phi \rho^{b} \times v^{a}}{\rho}.$$

Equation (140) agrees to $\frac{1}{15}$ th of the whole with twenty of Du Buât's experiments, his own formula agreeing so closely with only fifteen of them. The resistance must evidently increase with the number of bends or curves; but when they come close upon, and are grafted into each other, as in diagram 1, Fig. 41, and in the tube fbcdeg, Fig. 40, the motion in one bend or curve immediately affects those

^{*} Philosophical Transactions for 1808, pp. 173-175.

in the adjacent bends or curves, and this law does not hold.

Neither Du Buât nor Young took any notice of the relation that must exist between the resistance and the ratio of the radius of curvature to the radius of the pipe. Weisbach does, and combining Du Buât's experiments with some of his own, finds for circular tubes,

(143.)
$$h_b = \frac{\phi}{180} \times \left\{ \cdot 131 + 1 \cdot 847 \left(\frac{d}{2\rho} \right)^{\frac{7}{3}} \right\} \times \frac{v^3}{2g};$$
 and for quadrangular tubes,

(144.)
$$h_b = \frac{\phi}{180} \times \left\{ \cdot 124 + 3 \cdot 104 \left(\frac{d}{2\rho} \right)^{\frac{7}{3}} \right\} \times \frac{v^3}{2g};$$

in which ϕ is equal the angle N o P = N I R, diagram 2, Fig. 41; d the mean diameter of the tube, and ρ the radius N o of the axis. When $\frac{d}{2\rho}$ exceeds 2, the value

of :131 + 1:847
$$\left(\frac{d}{2\rho}\right)^{\frac{7}{3}}$$
 exceeds :124 + 3:104 $\left(\frac{d}{2\rho}\right)^{\frac{7}{3}}$,

and the resistance due to the quadrangular tube exceeds that due to the circular one. We have arranged and calculated the following table of the numerical values of these two expressions for the more easy application of equations (143) and (144). This table will be found of considerable use in calculating the values of equations (143) and (144), as the second and fifth columns contain the values of

 $\cdot 131 + 1.847 \left(\frac{d}{2\rho}\right)^{\frac{7}{3}}$, and the third and sixth columns the values of $\cdot 124 + 3.104 \left(\frac{d}{2\rho}\right)^{\frac{7}{3}}$, corresponding to

different values of $\frac{d}{2\rho}$; and it is carried to twice the extent of those given by Weisbach.

TABLE	o f	THE	VALUES	OF	THE	EXPRE	SSIONS

For bent tubes, diagrams 3, 4, and 5, Fig. 41, the loss of head is considerably greater than for rounded tubes. If, as before, we put the angle NIR = ϕ , IR being at right angles to IO the line bisecting the angle or bend, we shall find, by decomposing the motion, that the head $\frac{v^2}{2g}$ becomes $\frac{v^2}{2g} \times \cos^2 \phi$ from the change of direction; and that a loss of head (145.) $h_b = (1 - \cos^2 2\phi) \frac{v^2}{2g} = \sin^2 2\phi \frac{v^2}{2g}$ must take place. When the angle is a right angle, as in diagram 4, cos. $2\phi = 0$, and $h_b = \frac{v^2}{2g}$; that is to say, the loss of head is exactly equal to the

^{*} The values corresponding to $\frac{d}{2\rho}$ = .55 are .350 and .507 for circular and quadrangular tubes.

theoretical head. When the angle or bend is acute, as in diagram 5, the loss of head is $(1 + \cos^2 2 \phi \frac{v^2}{2g})$, for then $\cos 2 \phi$ becomes negative. Weisbach does not find the loss of head in a right angular bend greater than $984 \frac{v^2}{2g}$; while Venturi's twenty-third experiment, made with extreme care, p. 273, shows the loss to be $1.876 \frac{v^3}{2g}$. When the pipes are long, however, the value of $\frac{v^2}{2g}$ is in general small, and this correction does not affect the final results in any material degree.

Rennie's experiments,* with a pipe 15 feet long, \(\frac{1}{2} \) inch in diameter, and with 4 feet head, give the discharge per second

1.
$$v = .319 \sqrt{2g} \, \text{H}$$
, and therefore $H = 9.82 \times \frac{v^3}{2g}$;
2. $v = .282 \sqrt{2g} \, \text{H}$, ,, $H = 12.58 \times \frac{v^3}{2g}$;

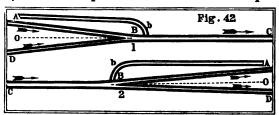

^{*} Philosophical Transactions for 1881, p. 488.

3. $v = .254 \sqrt{2g}$ H, and therefore H = $15.50 \times \frac{v^3}{2g}$; $H = 74.34 \times \frac{v^3}{2a}.$ 4. $v = 116 \sqrt{2 q H}$ The loss of head, therefore, by the introduction of 15 semicircular bends, is $2.76 \frac{v^2}{2a}$; by the introduction of one right angle, 5.68 $\frac{v^2}{2\sigma}$; and by the introduction of 24 right angles, $64.52 \frac{v^2}{2\sigma}$, or about 12 times the loss due to one right angle. shows that the resistance does not increase as the number of bends, as we before remarked, p. 256, when they are close to each other. The loss of head from one right angle, 5.68 $\frac{v^2}{2g}$, is more than double the loss from 15 semicircular bends, or $2.76 \frac{v^2}{2a}$. The loss of head for a right angular bend, determined from Venturi's experiment, is 1.876 $\frac{v^2}{2a}$; formula (145) makes it $\frac{v^2}{2a}$; and Weisbach's empirical formula, (9457 sin. $\phi + 2.047 \sin^4 \phi$) $\frac{v^2}{2a}$, makes it only •984 $\frac{v^2}{2a}$. The formulæ now in use give, therefore, results considerably under the truth. It appears to us, that the velocity of the water moving directly towards the bend must be taken into consideration, and also the loss of mechanical effect from contraction, and eddies at the bend, as

well as the loss arising from the mere change of direction.

BRANCH PIPES.

When a pipe is joined to another, the quantity of water flowing below the junction B, diagram 1, Fig. 42, must be equal to the sum of the quantities

flowing in the upper branches in the case of supply; and when the branch pipe draws off a portion of the water, as in diagram 2, the quantity flowing above the junction must be equal to the quantities flowing in the lower branches. Both cases differ only in the motion being from or to the branches, which, in pipes, are generally grafted at right angles to the main, for practical convenience, as shown at bb, and then carried on in any given direction. The loss of head arising from change of direction, equation (145), is $\sin^2 2 \phi \frac{v^2}{2a}$, in which $2 \phi = \text{angle Abo}$; but as in general 2 \phi is a right angle for branches to mains, this source of loss becomes then simply $\frac{v^2}{2a}$. addition to this, a loss of head is sustained at the junction, from a certain amount of force required to unite or separate the water in the new channel. In the case of drawing off, diagram 2, this loss was estimated by D'Aubuisson, from experiments by Génieys, to be about twice the theoretical head due

to the velocity in the branch, or $\frac{2v^2}{2g}$, so that the whole loss of head arising from the junction is $\frac{v^2}{2g} + \frac{2v^2}{2g} = \frac{3v^2}{2g}$, or three times the theoretical head due to the velocity. In the case of supply, the loss is probably nearly the same. The actual loss is, however, very uncertain; but, as was before observed when discussing the loss of head occasioned by bends, two or three times $\frac{v^2}{2g}$ is in general so comparatively small, that its omission does not materially affect the final results. A loss also arises from contraction, &c. See pp. 175, 176.

The calculations for mains and branches become often very troublesome, but they may always be simplified by rejecting at first any minor corrections for contraction at orifice of entry, bends, junctions, or curves. If, in diagram 2, Fig. 42, we put h for the head at B, or height of the surface of the reservoir over it; h_a for the fall from B to A; h_d for the fall from B to D; l equal the length of pipe from B to the reservoir; l_a equal the length BA; l_d equal the length BD; r equal the mean radius of the pipe BC; r_a the mean radius of the pipe BC; r_a the mean radius of the pipe BA; r_d the mean radius of BD; r_d the mean velocity in BC; r_d the reservoir in BC; r_d the reservoir to A equal to

(146.)
$$h + h_a = \left(c_r + c_t \times \frac{l}{r}\right) \frac{v^2}{2g} + \left(1 + c_t \times \frac{l_a}{r_a}\right) \frac{v_a^2}{2g}$$
; the fall from the reservoir to p equal to

(147.)
$$h + h_d = \left(c_r + c_t \times \frac{l}{r}\right) \frac{v^2}{2g} + \left(1 + c_t \times \frac{l_d}{r_d}\right) \frac{v_d^2}{2g};$$
 and, as the quantity of water passing from c to B is equal to the sum of the quantities passing from B to A and from B to D,

$$(148.) v r^2 = v_a r_a^2 + v_d r_d^2.$$

By means of these three equations we can find any three of the quantities h, h_a , h_d , r, r_a , r_d , b, b_a , b_d , the others being given. Equations (146) and (147) may be simplified by neglecting c_r , the coefficient due to the orifice of entry from the reservoir, and 1, the coefficient of velocity. They will then become

(148A.)
$$h + h_{\bullet} = c_{t} \times \left(\frac{l}{r} \times \frac{v^{3}}{2g} + \frac{l_{\bullet}}{r_{\bullet}} \times \frac{v^{3}}{2g}\right),$$

and

$$(149.) h + h_d = c_t \times \left(\frac{l}{r} \times \frac{v^3}{2q} + \frac{l_d}{r_d} \times \frac{v_d^3}{2q}\right).$$

The mean value of c_t for a velocity of 4 feet per second is 005741, and of $\frac{c_t}{2g}$, 0000891. The values for any other velocities may be had from the table of coefficients of friction given at p. 214. When l, h, and r are given, the velocity v can be had from the equation, $v = \left(\frac{2g}{c_t} \times \frac{rh}{l}\right)$, or more immediately from Table VIII.

GENERAL EQUATION FOR MEAN VELOCITY.

We are now enabled to give a general equation for finding the whole head n, and the mean velocity v, in any channel; and to extend equations (73) and (74) so as to comprehend the corrections due to bends,

curves, &c. Designating, as before, the height due to the resistance at the orifice of entry by

 h_r , and the corresponding coefficient by c_r ;

 h_t the head due to friction, and c_t the coefficient of friction;

 h_b the head due to bends, and c_b the coefficient of bends;

 h_c the head due to curves, and c_c the coefficient of curves:

 h_e the head due to erogation, and c_e the coefficient of erogation;

 h_x the head due to other resistances, and c_x their mean coefficient;

then we get

(150.)
$$H = h_r + h_t + h_b + h_c + h_c + h_x + \frac{v^2}{2g}$$
; that is to say, by substituting for h_r , h_b &c., their values as previously found,

$$\begin{split} \mathbf{H} &= (1+c_{\rm r}) \, \frac{v^2}{2\,g} + c_{\rm f} \frac{l}{r} \times \frac{v^2}{2\,g} + c_{\rm b} \times \frac{v^2}{2\,g} \\ &+ c_{\rm c} \times \frac{v^2}{2\,g} + c_{\rm c} \times \frac{v^2}{2\,g} + c_{\rm x} \times \frac{v^2}{2\,g}; \end{split}$$

or, more briefly,

(151.)
$$H = (1 + c_r + c_t \times \frac{l}{r} + c_b + c_c + c_c + c_z) \frac{v^2}{2g}$$
; from which we find

(152.)
$$v = \left\{ \frac{2 g H}{1 + c_r + c_t \times \frac{l}{r} + c_b + c_e + c_e + c_x} \right\}^{\frac{1}{2}}$$

It is to be observed here, that for very long uniform channels, the value of the mean velocity will be found in general equal to $\left\{\frac{2grH}{c_ll}\right\}^{\frac{1}{2}}$, as the other resistances and the head due to the velocity are all trifling compared with the friction, and may be rejected without error; but, as we before stated, it is advisable in practice, when determining the diameter of pipes, p. 229, to increase the value of c_0

table, p. 214, or to increase the diameter found from the formula by one-sixth, which will increase the discharging power by one half. (See TABLE XIII.)

In equations (74) and (151), the coefficient of friction c_r depends on the velocity v, and its value can be found from an approximate value of that velocity from the small table, p. 214. If, however, we use both powers of the velocity, as in equation (83), we shall get, when H is the whole head, and h the head from the surface to the orifice of entry

$$(a v + b v^2) \frac{l}{r} + (1 + c_r) \frac{v^2}{2 g} + h = H,$$

a quadratic equation from which we find

$$v = \left\{ \frac{(\mathbf{H} - h) 2 g r}{(1 + c_r) r + 2 g b l} + \left(\frac{gal}{(1 + c_r) r + 2 g b l} \right)^2 \right\}^{\frac{1}{6}} - \frac{gal}{(1 + c_r) r + 2 g b l}$$

for a more general value of the velocity than that given in equation (74). If now we put $c_{\bullet} = c_{r} + c_{b} + c_{o} + c_{o} + c_{s}$ in equation (151) we shall find

$$v = \left\{ \frac{(\mathbf{H} - h) 2 g r}{(1 + c_a) r + 2 g b l} + \left(\frac{gal}{(1 + c_a) r + 2 g b l} \right)^2 \right\}^{\frac{1}{2}} - \frac{gal}{(1 + c_a) r + 2 g b l}$$

for a more general expression of equation (152), when the simple power of the velocity, as in equation (83), is taken into consideration. For measures in English feet, we may take a = .0000223 and b = .0000854, which correspond to those of Eytelwein, in equation (97). The value of a is the same in English as in French measures, but the value of b in equation (83), for measures in metres, must be divided by 3.2809 to find its corresponding value for measures in English feet. In considering the head $\frac{v^2}{2g}c_r$, due to contraction at the orifice of entry as not implicitly comprised in the primary values of a and b, equation

(83), Eytelwein is certainly more correct than D'Aubuisson, Traité d'Hydraulique, pp. 223 et 224, as this head varies with the nature of the junction, and should be considered in connection with the head due to the velocity, or separately. It can never be correctly considered as a portion of the head due to friction. In all Du Buât's experiments, this head was considered as a portion of that due to the velocity, and the whole head, $(1 + c_r) \frac{v^2}{2a}$, deducted to find the head due to friction and thence the hydraulic inclination.

These mean values of a and b give the equation $rs = .0001040 v^2 + .0000221 v$

from which we find

$$9615 \, r \, s = v^2 + \cdot 21 \, v,$$

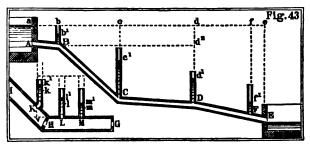

and thence

Mean

(153.) $v = (9615 \, rs + \cdot 011)^{\frac{1}{2}} - \cdot 105 = 98 \, \sqrt{rs} - \cdot 1$, very nearly, suited to velocities of about 2 feet, p. 217.

HYDROSTATIC AND HYDRAULIC PRESSURE, -PIEZOMETER.

When water is at rest in any vessel or channel, the pressure on a unit of surface is proportionate to the head at its centre,* measured to the surface, and is expressed in lbs. for measures in feet, by $62\frac{1}{2}$ H s, in which H is the head, and s the surface exposed to the pressure, both in feet measures. This is the hydrostatic pressure. In the pipe A B C D F E, Fig. 43, the pressure at the points B, C, D, F, and E, on the sides of the tube will be respectively as the heads B b, C c, D d, F f, and E e, if all motion in the tube be prevented by

stopping the discharging orifice at E. In this case the pressure is a maximum and hydrostatic; but if the discharging orifice at E be partially or entirely open, a portion of each pressure at B, C, D, F, &c., is absorbed in overcoming the different resistances of friction, bends, &c., between it and the orifice of entry at A, and also by the velocity in the tube, and the difference is the hydraulic pressure.

* This is only correct when the surface is small in depth compared with the head. If H be the depth of a rectangular surface in feet, and also the head of water measured to the lower horizontal edge, then the pressure in lbs. is expressed by 31½ H²; and the centre of pressure is at \frac{3}{2} rds of the depth.

Bernoulli first showed that the head due to the pressure at any point, in any tube, is equal to the effective head at that point, minus the head due to the velocity. When the resistances in a tube vanish, the effective head becomes the hydrostatic head, and by representing the former by $h_{\rm ef}$ we shall have, adopting the notation in equation (150),

$$h_{\rm ef} = H - (h_{\rm r} + h_{\rm f} + h_{\rm o} + \&c.),$$

and consequently the head due to the hydraulic pressure equal

(153A.)
$$h_{\rm p} = h_{\rm ef} - \frac{v^2}{2g} = H - (h_{\rm r} + h_{\rm f} + h_{\rm b} + \&c.) - \frac{v^2}{2g}$$

If small tubes be inserted, as shown in Fig. 43, at the points B, C, D, and F, the heights B b^1 , c^1 , c^1 , c^1 , c^1 , which the water rises to, will be represented by the corresponding values of h_p in the preceding equation; and the difference between the heights c^1 , c^1 , at c^1 and c^2 , for instance, added to the fall from c^2 to c^2 will, evidently, express the head due to all the resistances between c^2 and c^2 . When c^2 and the orifice at c^2 is open, we have, from equation (150), c^2 c^2 and therefore c^2 and the fall from c^2 to c^2 and the orifice at c^2 is open, we have, from equation (150), c^2 that is, the pressure at the discharging orifice is

The vertical tubes at B, C, D, F, when properly graduated, are termed *piëzometers* or *pressure gauges*; they not only show the actual pressure at the points where placed, but also the difference between any two; $Dd^1 - Bb^1$, for instance, added to the difference of head between D and B, or Dd^2 will give $Dd^1 - Bb^1 + Dd^2$ for the head or pressure due to the resistances

nothing.

between B and D. This instrument affords, perhaps, the very best means of determining the loss of head due to bends, curves, diaphragms, &c. The loss of head due to friction, bend, diaphragms, &c., between K and L, Fig. 43, is equal to Kk - Ll + Kv. If M be the same distance from L as K is, Ll - Mm will be the height due to the friction (L and M being on the same level); therefore Kk - Ll + Kv - Ll + Mm = Kk + Kv + Mm - 2Ll is the head due to the diaphragm and bend both together. If the diaphragm be absent, we get the head due to the bend, and if the bend be absent, the head due to the diaphragm in like manner.

When the discharging orifice, as at E, is quite open, we have seen that the pressure there is zero; but when, as at G, it is only partly open, this is no longer the case, and the hydraulic pressure increases from zero to hydrostatic pressure, as the orifice decreases from the full section to one indefinitely small compared with it. A piëzometer, placed a short distance inside G, will give this pressure; and the difference between it and the whole head will be the head due to the resistances and velocity in the pipe: from which, and also the length and diameter, the discharge may be calculated as before shown. Again, by means of the head m m1, and that due to the velocity of approach, we can also find the discharge through the diaphragm G; see equation (45) and the remarks following it. This result must be equal to the other, and we may in this way test the formulæ anew or correct them by the practical results.

The velocity of discharge of the tube A C D E, may

be calculated by means of any piëzometric height $c c^1$; for by putting the whole fall from c^1 to $equal to H_{c^1}$, we get, disregarding bends, $v = \left\{\frac{2 g r H_{c^1}}{c_t l_{c^1}}\right\}^{\frac{1}{4}}$, in which $l_{c^1} = c e$. This is evident from equation (152), as we have supposed that no part of the head is absorbed in generating velocity, or in overcoming the resistance of bends. If the bend at $ext{D}$ were taken into consideration, then $ext{D} = \left\{\frac{2 g H_{c^1}}{c_t \times \frac{l_{c^1}}{c_t} + c_b}\right\}^{\frac{1}{4}}$.

SECTION XII.

RAIN-FALL.—CATCHMENT BASINS.—DISCHARGE INTO CHANNELS.
—DISCHARGE FROM SEWERS.—LOSS FROM EVAPORATION, ETC.

A catchment basin is a district which drains itself into a river and its tributaries. It is bounded generally by the summits of the neighbouring hills, ridges, or high lands forming the water-shed boundary; and may vary in extent from a few square miles to many thousands; that of the Shannon is 4,544 square miles. The average quantity of water which discharges itself into a river will, cæteris paribus, depend on the extent of its catchment basin, and the whole quantity of rain discharged on the area of the catchment basin, including lakes and rivers.

The quantity of rain which falls annually varies with the district and the year; and it also varies at different parts of the same district. The average quantity in Ireland may be taken at about 34 inches

deep, that which falls in Dublin being 27 inches, and that in Cork 41 inches nearly. The average yearly fall in Dublin for seven years, ending with 1849, was 26.407 inches; and the maximum fall in any month took place in April 1846, being 5.082 inches. average fall in inches per month for seven years, ending with 1849, was as follows: -October, 3.060; August, 2.936; January, 2.544; April, 2.503; November, 2.300; July, 2.116; June, 2.005; December, 1.938; September, 1.860; May, 1.814; March, 1.739; February, 1.534." A gauge at Londonderry, 1795 to 1801, gives 31 inches average; one at Belfast, from 1836 to 1841, gives 35 inches; at Mountjoy, Phœnix Park, 182 feet above low water. 1839 and 1840, there is an average of 33 inches; and at the College of Surgeons, 52 feet over low water, the average is 30 inches for the same two years. Sir Robert Kane assumes that 36 inches is the average fall in Ireland, and that out of that depth 12 inches, or one-third, passes on to the sea, twothirds being evaporated and taken up by plants. The quantity varies a good deal with the altitude of the district. In parts of Westmoreland it rises sometimes to 140 inches; in London, an average of 20 years' observations, gives a fall of nearly 25 inches.

Forty years' observation at Greenwich, Kent, at 155 feet above the level of the sea, gives the following results:—

υ3

^{*} Proceedings of the Royal Irish Academy, vol. v., p. 18.

Description of fall.	Winter.	Spring.	Summer	Entire Years.
	inches.	inches.	inches.	inches.
Mean annual fall	7.86	7.25	10.47	25·48 25·58
Maximum fall; being a mean of five of the wettest years during forty years	11-05	10-86	14-96	{ 34·00 36·87
five of the driest years during forty years	5.22	4 ·05	6-80	{ 18·40 16·07

In this table Winter comprises November, December, January, and February; Spring, the next four months; and Summer, the months of July, August, September, and October. The last column contains means of two classes of years: the first figures showing the ordinary years from January to December, and the second, under the first, years from November to October.* We see here that the mean maximum is fully double of the mean minimum, and about one-and-a-half times the mean annual fall, and therefore the necessity for calculating from the minimum fall for all water works in which it is an element, and from the maximum for sewerage works where it is not intended to pass off a portion on the surface or through other available channels.

In the district surrounding the Bann reservoirs in the County Down, the average fall has been so high as 72 inches. In Keswick, the average fall is said to be 67½ inches, and in Upminster, Essex, only 19½ inches. Indeed, it is requisite to obtain the fall from observation for any particular district, when it

^{*} See Mr. James Simpson in the Metropolitan Main Drainage Report, 1857, p. 115.

is necessary to apply the results to scientific purposes; and not the mean average fall alone, but also the maximums and minimums in a series of years and months in each year.

Mr. Symons gives (see Builder for 1860, p. 230) the following heavy falls of rain during 1859:— Wandsworth, June 12th, 2·17 inches in two hours; Manchester, August 7th, 1·849 inches in twenty-four hours; Southampton, September 26th, 2·05 inches in two-and-a-quarter bours; Truro, October 25th, during the day, 2·4 inches. The mean falls in the South Western Counties were 39·1 inches; in the South Eastern Counties, 30·2 inches; in the West Midland Counties, 28 inches; in the Eastern Counties, 25·4 inches; in the North Midland Counties, 24 inches; in the North Western Counties, 39 inches; in the Northern Counties, 55 inches; and the average of all England, 31·857 inches.

As an instance of extraordinary rain-fall, in connexion with the sewage question, it is stated that 4 inches of rain fell in one hour in the Holborn and Finsbury sewers' district, on the 1st of August, 1846; at Highgate, 3.5 to 3.3 inches; and at Greenwich, 0.95 inches.*

In the upland districts about Manchester, Mr. Homersham† gives the result of observations at Fairfield, Bolton, Rocksdale, Marple, Comlis reservoir, Belmont, Chapel-en-le-Frith, and Whiteholme reservoir, for four years. These give a maximum fall of 61.4 inches at Belmont Sharples in 1847, and

^{*} Metropolitan Main Drainage Report, p. 16.

[†] Report on the Supply of Water to Manchester.—Weale.

a minimum of 24.8 at Whiteholme reservoir in 1844. The general average for the four years being 42.49 inches.

April is the driest month, and October, or about it, the wettest month, and the average fall during the year varies sometimes as two to one.

The proportion between the quantity which falls, and that which passes from a catchment basin into its river, also varies very considerably. When the sides of a catchment basin are steep, and the water passes off rapidly into the adjacent river or tributaries, there is less loss by evaporation and percolation than when they are nearly flat. The soil, subsoil, and stratification, have also considerable effect on the proportion. Reservoirs being generally constructed adjacent to steep side falls, give a much larger proportion of the quantity fallen than can be obtained from rivers in flatter districts; besides, the quantity of rain which falls on the high summits, near reservoirs, almost always considerably exceeds the average fall. As 640 acres is equal to one square mile, and one acre is equal to 43,560 square feet, a fall of one inch of rain is equal to 3,630 cubic feet per acre, and to $3,630 \times 640 = 2,323,200$ cubic feet per square mile: the proportion of this fall, for each acre, or square mile of the catchment basin, which enters the river, must depend entirely on the district and local circumstances, the full or maximum quantity being retained on lakes. A stream delivering 53 cubic feet per minute supplies an equivalent to 12 inches of rain-fall collected per square mile per annum.

It is too often taken for granted that the discharge from a catchment basin takes place, into the conveying channels, in nearly the same time that a given quantity of rain falls. Perhaps the largest registry on record in Great Britain is a fall of four inches in an hour. The maximum fall in any hour of any year seldom exceeds half of this amount, and then perhaps only once in several years. The quantity which falls will not be discharged into the channels in the same time. The quantity discharged,

QUANTITY PER ACRE FOR A GIVEN DEPTH OF FALL.

and time, will depend a good deal on the season and district. The arterial channel receives the supply at different places and from different distances, and the water in passing into and from it does not encounter the same amount of resistance as if it all passed first into the upper end. Less sectional area is therefore necessary than if the whole discharge had to pass through the whole length of the channel and during the time of fall. The relation of the quantity of rain-fall to the portion which flows into the main channel, as well as the time which it takes to arrive at it, and the places of arrival, must be known

before the proper size of a new channel can be determined, particularly sewers in urban districts. A pipe sufficient to discharge the water from 200 acres need not be 20 times the discharging power of one exactly suited to 10 acres of the same district, for the discharge from the outlying 190 acres will not arrive at the main in the same time as that from the adjacent 10 acres.

The following table of rain-fall, at Athlone, central in Ireland, was furnished to the Royal Irish Academy by General Sir H. D. Jones, and is printed in the Proceedings.* The average for four years, gives 29 inches, and the effect on the Upper and Lower Sills of the Lock as affecting the rise and fall of the Shannon, affords valuable data, although not analysed. The rise and fall on the sills is the sum of the monthly risings and fallings for each year, and must be divided by 12 to get the average monthly rise and fall. In 1845 the greatest rise was in January, 2 feet 9 inches at the upper sill, and 3 feet 11½ inches at the lower sill. In 1846 the greatest rise was 2 feet 5 inches in October, at the upper sill; and 5 feet 6½ inches on the lower sill, in August.

			Upper Sill.	Lower Sill.

at either sill. The general average of the rise and fall for the upper sill, is about 1 foot 3½ inches each way, and 1 foot 10½ inches at the lower sill. These would give 2 feet 7 inches for the average difference of level in the Shannon above, and 3 feet 9½ inches for that in the Shannon below. In Lough Allen catchment of 146 square miles, the maximum rise was sometimes 6 inches in 24 hours, calculated at 568 inch of depth of rain, over the catchment area. Above Killaloe, the catchment is 3,611 square miles, and the floods about once a year rose 6 inches in 24 hours, or 296 inch in depth of rain over the catchment. Once, in 1840, it is reported to have risen 12 inches, or 6 inch of rain over the catchment in one day.

MAXIMUM DISCHARGES OF THE SHANNON AND ERNE, AND A TRIBUTARY OF THE LATTER,
THE WOODFORD RIVER.

These results show how difficult it is to draw any inference from discharge and area of catchment alone, as the discharge, per minute per acre, must vary with the contour and elevation of the district in the same course; and with the climate also, in different countries. We have observed ourselves the maximum discharges to vary up to 6 cubic feet per minute per acre, the lesser maximums being due to broad flat districts, and the greater maximums to higher and steeper districts, near the sources. the Proceedings of the Institution of Civil Engineers, Ireland, vol. iv., from which we have collected and arranged some of the foregoing information, it is stated, p. 96, that the ratio of the discharge to the rain-fall, on a catchment on the Glyde, of 79,433 acres, for three months, ending March 13th, 1851, was 1.49 to 1 up to January 13th; 1.39 to 1 up to February 13th; and 3.86 to 1 up to March 13th, making a general average of 1.59 to 1; the whole rain-fall for the three months being only 5.89 inches, while the discharge was 9.35 inches! We fancy there is a mistake here. The whole catchment of the Glyde is 176,813 acres, and there is no data to show the discharge previous to or after the rain-fall from which to calculate the difference due to it per se for the three months; nor is the place or method of gauging stated. The supply from springs and the actual discharge before and after rain-fall must be correctly gauged before the proportion passing into the main channel in a given time, can be properly estimated; the results just stated clearly contradict themselves. The following anomalous results

from p. 47 of the same work are also worthy of note. In five different districts the discharge is gauged, or estimated, greater than the fall, as shown in the following table. It is not stated, however, if

			DECEMB	er 1850.	JANUAR	т 1851.

the depths passed off, estimated over the catchments, include the flow before the commencement of the rain. If so the results are so far useless; and if they do not include it, there must be an error somewhere. Indeed, in the Robe we have evidence that not more than 58 per cent. passed from the catchment to the river, from Mr. Betagh's paper, the results of which are arranged below. Also, in July 1850, it is shown that in the Lannagh district only 53 inch in depth passed off the catchment from a fall of 1.83 inches, or about one-third of the depth. The method of determining this was unobjectionable. Where such discrepancies as above exhibited exist, it is important that the method of gauging, and the whole calculation, should be shown, in order that other engineers should be able to judge

of their accuracy; otherwise the results should be rejected, no matter under whose authority they may be published.

The following information has been collected and arranged by us from a paper by Mr. Betagh, in the Proceedings of the Institution of Civil Engineers, Ireland, vol. iv. In January 185I, 3.41 inches of rain fell in seven days, producing the maximum discharge of 85,836 cubic feet; while in December 1852, 3:17 inches, also falling in seven days, produced 115,656 for the maximum. At the beginning of the first fall there was flowing 26,640 feet, leaving the effects of the seven days' rain 85,836 - 26,640= 59,196 cubic feet, while in the second year the quantity flowing at first was 75,360 cubic feet, leaving the effects of the seven days' rain-fall equal to 115,656 - 75,360 = 40,296 cubic feet. The effect of the previous state of the weather on the catchment must always modify, to a considerable extent, the discharge from a given rain-fall, and this has more to do with the results than the effect of arterial drainage itself, unless so far as one is a result of the other. Taking the mean of 1851 and 1852, it appears that the evaporation in the Ballinrobe catchment was to the rain-fall as 41.6 to 98.7, or about 42 per cent. This is certainly, from the nature of the catchment, less than the average through Ireland, which cannot be less than 60 per cent. In high, steep districts, fully three-fourths or 75 per cent. of the rain-fall can be collected, and at times, when the catchment is saturated, nearly the whole; even in some few limited cases, when springs or hidden

TABLES showing in detail, for the years 1851 and 1852, the Monthly Fall of Rain and the corresponding Discharge of the River Robe, at Ballinrobe, County Mayo; the catchment basin being 70,000 acres, or 110 square miles; the lower end 100 feet, the upper end 336 feet; and the average height of the surface about 180 feet above the level of the sea. The average fall of the river, not including the rapids, is from one to two feet per mile; the catchment is about 20 miles long, about one-tenth of the area bog or low marsh, and nine-tenths clayey and gravelly. The river is about 33 miles long.

north side of the Thames is about 75 persons per acre, and on the south side 28 persons per acre. Taking the average density of population in our twenty-one principal towns, there appear to be 5045 inhabitants to the square mile; but, from the following table, extracted from Dr. Duncan's report on Liverpool, it will be seen that if we select five of our most populous cities, the average in these is much greater, while in others, it is equally certain that the crowding is far less than the general standard to which we have referred:—

	Inhabitants to a	Square Mile.
Towns.	Total Area.	Builded Area
Leeds	. 20,892 .	. 87,256
London	. 27,423 .	. 50,000
Birmingham .	. 33,669 .	. 40,000
Manchester	. 83,224 .	. 100,000
Liverpool	. 100,899 .	. 138,224

Dr. Duncan, however, states that there is a district in Liverpool containing 12,000 inhabitants crowded together on a surface of only 105,000 square yards, which gives a ratio of 460,000 inhabitants to the geographical square mile. In the East and West London Unions, Mr. Farr has estimated that there are nearly 243,000 inhabitants to a geographical square mile; but, great as this overcrowding is, the maximum density of Liverpool exceeds that of the metropolis by nearly double."*

The amount of sewage from each person is calculated about five cubic feet per person, including the supply from manufactories, breweries, distilleries, &c. Seven feet per head has been recommended as data to calculate from by Captain Galton, Messrs. Simpson and Blackwell, in their Report on the Main Drainage, and it has been found that about half of the estimated quantity of sewage would pass off in six or eight hours.

In calculating the size of sewers, however, the rain-fall must be provided for, in addition to the sewage matter from houses and public establishments. Mr. Bazalgette calculated this for the London sewerage at 4th of an inch fall in 24 hours in the urban districts, and 4th of an inch for the suburban districts. Captain Galton and the Messrs.

[•] Illustrated News, September 8th, 1855.

Simpson and Blackwell assumed \$\frac{2}{3}\$ths of an inch fall during eight hours' maximum flow. This would be 1452 feet per acre. Assuming the highest data, we shall have to provide sewers to discharge in eight hours

1,452 cubic feet of rain water per acre,
3½ cubic feet of sewage nearly per person.
Assuming a population of 80 persons per acre, then
these figures would become

1,452 cubic feet for rain,
280 cubic feet for sewage,
which shows that the sewage is not more than ith of the rain water; and that, in calculations for the size of sewers, the surface water is the most important element to be considered. If we had assumed a larger fall of rain, the difference between sewage and rain would be greater. On the 20th June, 1857, the day after heavy rain, the referees on the Metropolitan Drainage question found the Norfolk-street sewer to discharge 3 feet; the Essex-street sewer 5½ feet; the Northumberland-street sewer 3½ feet; and the Savoy-street sewer 20½ feet per minute per acre; but the last result has been controverted.

It appears that the daily amount of sewage varies from 4.8 cubic feet per head in the more thickly inhabited portions of London, occupied by a larger portion of the poorer classes, to 8 cubic feet per head in the western districts, where the value of water is more appreciated, and the cost less a matter of consideration; and the average of the whole

metropolitan districts appears to be 5.8 cubic feet per head per diem. If the day be divided into three periods of eight hours each, the amount of the maximum flow is between nine A.M. and five P.M. and 49 per cent. of the whole, whilst only 18 per cent. flows during the eight hours of minimum flow, which occur between eleven P.M. and seven A.M.* The advantage of storm flows in flushing is shown by the heavy rain which occurred on the 20th of June, causing a flow in the Savoy-street sewer.which was equivalent to 20 times the ordinary flow at the time. This was six times the maximum flow, and although the sewer had been scoured, to a considerable extent, by a heavy fall of rain on the previous night, the sample contained more than double the amount of total impurity contained in specimens of ordinary sewage.

In a town district, such as that drained by the Savoy and Northumberland-street sewers, the quantity running off into sewers, within six hours after the fall, varies from 10 to 60 per cent. of the quantity fallen. Of the rain during the storm of the 20th June, 1857, nearly one inch-and-a-quarter in an hour, 65 per cent., ran off within 15 hours of the fall, viz.:—

46 per cent. in 45 minutes after the rain ceased,

- in the next 64 hours,
 - 5, in the next 7½ hours.

In a suburban locality, such as the Counter Creek sewer drain, the quantity reaching the sewers would

^{*} Metropolitan Main Drainage Report, pp. 15, 17.

vary from 0 to 30 or 40 per cent. in 24 hours after the rain.*

In the Holborn and Finsbury divisions Mr. Roe calculated that an 18-inch cylindrical pipe, laid at an inclination of 1 in 80, is sufficient for 20 acres of house-sewage, while a 5-inch pipe, laid at an inclination of 1 in 20, is necessary for 1 acre, and a 3-inch pipe, laid also at 1 in 20, for 1 acre. A pipe 30" in diameter, laid with an inclination of 1 in 200, would discharge 1700 cubic feet per minute, and perfectly drain 200 acres of urban land covered with houses to the extent of 4000 or upwards, and each house having a water supply of 150 gallons per diem. In each of these cases, however, the discharge must depend on the head and length of the pipe as well as the inclination at which it is laid. Assuming the inclination of those pipes to correspond with the hydraulic inclination, we have calculated their discharging powers with water to be respectively 807, 72, 20, and 1700 cubic feet per minute, the areas to be drained being 20, 1, 1, and 200 acres. In all calculations of this kind it is necessary, for accuracy, to ascertain not only the maximum rain-fall per hour, but also the proportions discharged per hour, according to the season and district, into the main channel, as well as the junctions or places of arrival. In urban districts, 1500, 2100, and sometimes 3600 cubic feet per hour per acre, have to be discharged after extraordinary rain-falls. These may be taken as maximum results. The

^{*} Metropolitan Main Drainage Report, pp. 75, 76.

gaugings of the Westminster sewers in summer give 53 cubic feet per hour for the urban, and 17 feet for the suburban, according to Mr. Hawkins.

In urban districts, however, a much larger quantity of water is conveyed more rapidly, cæteris paribus, to the mains, than in suburban districts and catchment basins generally, in which the maximum discharge per acre per hour, even in the steeper and higher districts, seldom exceeds 700 cubic feet, and varies from about 20 cubic feet for the larger and flatter districts upwards. This arises from the impervious nature of the surfaces it falls upon in towns, and the lesser waste in passing to the drains, as well as a large portion of the supply being often artificial. From 70 to 90 cubic feet* per acre per hour, is generally taken for the maximum discharge from the average number of catchment basins; this is nearly equal to a supply of one-fiftieth part of an inch in depth from the whole area. Thorough-drainage increases the supply and discharge. Every catchment basin has, however, its own peculiar data, and a knowledge of these is necessary before we can draw any correct conclusions for new waterworks in connection with it. It may be remarked, however, that any conclusions drawn from experiments on the supply of tributaries, particularly in high districts, are wholly inapplicable to the main channel into which they flow. The flow into tributaries and mountain streams, or rivers, is always more rapid than into

^{*} Some interesting observations on rain-fall and flood discharges are given in the Transactions of the Institution of Civil Engineers, Ireland, for 1851, pp. 19-33, and pp. 44-52.

main channels and rivers in flat districts, and the supply from springs often forms a large portion of the water flowing in them.

TABLE showing Summer Discharges of some English Rivers, as collected from various authorities, re-arranged, showing to some extent the effect of Springs in supplying Channels in different places.

The above information has been obtained from Mr. Beardmore and Mr. Hughes' books, and from Rennie's reports. The effect of the geology and fissures in the chalk and mountain limestone formations on the springs of a catchment basin, and on maintaining the summer discharge, should be carefully noted as one of the elements entering into catchment basin statistics. Indeed, the maximum and minimum discharges from catchments are of as much importance to the engineer as the averages, and, for many purposes, more important. There were abundant opportunities of acquiring this information for all our Irish rivers, but we are not aware if these were turned to account.

The effects of evaporation are very variable; sometimes 58 or 60 per cent. of the annual fall is carried off in this way from ordinary flat tillage soils, and other estimates are much higher; much, however, depends on the soil, subsoil, inclination, stratification, and season. The evaporation from water surfaces exceeds the annual fall in these countries by about one-third; and that from flat, marsh, and callow lands exceeds the evaporation from ordinary tillage, porous, and high lands. When the flat lands along the banks of rivers extend considerably on both sides, an extra fall is necessary into the main channel, along the normal drains, otherwise such lands must suffer from excessive evaporation as well as floods. Evaporation also varies with the climate, and in this country we may assume that one-third of the whole rain-fall passes on to the sea.

In a paper in the Journal of the Royal Agricultural

Society of England, vol. v, part 1, 1844, Mr. Josiah Parkes shows, that 42½ per cent. of the whole annual rain of England filters through the soil, and 57½ per cent. evaporated, being the mean results of eight years' observations, from 1836 to 1843, both included. The mean evaporation and filtration for each month during this period is shown and arranged by us in the following table:—

MONTHS.	Total falling.	Evapo	rated.	Rema	ining.	Deposited and Cubic act	feet per

The maximum quantity, 32·10 inches, fell in 1841, and the minimum in 1837, 21·10 inches. The maximum quantity which fell in January was 3·95 inches, and the minimum ·31 inch; in February 2·85 and 1·02 inches; in March 3·65 and 0·34 inches; in April, 2·57 and ·34 inches; in May 5·00 and ·70

inches; in June 3·31 and 1·33 inches; in July 4·36 and 1·30 inches; in August 3·65 and 0·95 inches; in September 4·50 and 0·63 inches; in October 4·82 and 1·41 inches; in November 5·77 and 2·05 inches; and in December 3·02 and ·40 inches. The greatest quantities fall in September, October, and November; and the least in February, March, and April. The general mean fall for England is said to be 31½ inches, and near London 25 inches.

The amount of rain varies, not only at different places and different elevations, but also at different elevations in the same place. The following table shows the amount of rain collected in each month in 1855 at Greenwich observatory, at different elevations:

MONTH IN 18	55.		Osler's anemo- meter gauge, inches.	On the roof of the library.	Cylinder partly sunk in the ground.
January		•••	0.2	1.0	1.5
February		•••	0.2	1.4	1.0
March		•••	0.5	1.8	2.0
April		•••	0.1	0-1	0-1
Мау		•••	0.5	1.5	1.8
June		•••	0.5	0-7	0-9
July			8.1	4.8	5.8
August		•••	0.8	0.8	1.4
September		•••	0.8	1.1	2.0
October	•••	•••	2.6	4.5	5-2
November	•••	•••	0.2	1.1	1.2
December	•••	•••	0.4	0-9	1·1
Totals		•••	10.0	19:2	23.8

The cylinder gauge was placed 155 feet above the

level of the sea; the gauge on the roof of the library 22 feet over the cylinder gauge, and Osler's anemometer gauge 28 feet higher than the gauge on the roof of the library. In the valleys in the lake districts, Westmoreland and Cumberland, the annual fall varies occasionally from 50 to 100 inches, and the maximum fall is said to obtain at about 2000 feet above the level of the sea on high catchments.

At Ballinrobe, a gauge placed on the church tower, 60 feet above the ground, indicated 42 per cent. less rain than one on the ground; and another experiment with a change of gauges, gave 68 per cent. less at the greater elevation.

At Kinfauns Castle, Scotland, a gauge 600 feet high on a hill, gave 41½ inches, while one at the base, 580 feet lower, gave only 25½ inches. In Keswick, the fall is 65½ inches, and in Carlisle only 30 inches. At Kendall the fall is 60 inches; at Manchester 33 inches; at Lancaster 45 inches; at Liverpool 34 inches.

From the 23rd of February to the 6th of June, 1860, the rain at Dublin was 8 inches. At the Leefin Mountain, which is 2000 feet high, the rain was 13·1 inches. From the 23rd of February to the 9th of July, the rain at Dublin was 10·674 inches; and at the same time, on the Leefin Mountains (over Ballysmutten), 18·1 inches; that is, an increase of nearly 80 per cent. in that time. From the 23rd February to the 21st August, inclusive, the rain-fall at Dublin was 17 inches; at Blessington 21 inches; at Ballysmutten, on the site of a proposed reservoir, 27 inches. This showed an increase over Dublin of 10 inches. It would appear that from 50 to nearly 80 per cent. more rain fell at Ballysmutten than at Dublin.

Experiments were made at York in 1832, 1833, and 1834, for the British Association, with three gauges,—the first placed on a large grass plot in the grounds of the Yorkshire Museum; the second at a higher elevation, 43 feet 8 inches, on the roof of the Museum; and the third on a pole 9 feet above the battlements of the great tower of the Minster, at an elevation over the gauge on the ground of 212 feet 10½ inches. The quantities received were as follows:—

		1	Depth for			Average do	ar.
First gauge	•	•	64.430	inches		21·477 i	nches
Second gauge			52.169	,,	•	17.389	,,
Third gauge			38.972	,,		12.991	,,

Professor Phillips gives the following formula for calculating the difference between the ratios of rain falling on the ground and at any height h in the same place— t^c the temperature of the season, and c a coefficient dependent upon it; then the difference d is

$$d = c h \frac{t^{\circ}}{110}.$$

The mean height at which rain begins to be formed by this formula is 1,747 feet over the ground; and at 356 feet high, the depth which falls is one-half of what falls on the ground.*

A discussion of the mean temperature in connexion with the fall of rain, has been made at Greenwich for the years 1852, 1853, and 1854; and at Oxford for the years 1855, 1856, and 1857. The result shows an average of 160.3 rainy days at Greenwich for each year, and 146.6 at Oxford. The difference of the mean temperatures of the day of rain and the day before is less than that of the day of rain and the day after.

^{*} Vide Civil Engineer and Architect's Journal for 1860, p. 167.

		Iean tempera- ture, day before rain.	1	Mean tempera- ture, day of rain.	M	Iean tempera- ture, day after rain.
Greenwich	observations	49·25°		49.270		48·98°
Oxford	do.	49.50		49.63		49.44

Dividing the winds into two groups, northerly and southerly, the Oxford observations give the direction for 218.5 days' fair weather. The wind was northerly for 131.5 days, and southerly for 87 days. For the remaining 146.5 rainy days, the wind was northerly for 64.5 days, and southerly for 82 days.

SECTION XIII.

WATER SUPPLY FOR TOWNS.—STRENGTH OF PIPES.—SEWER-AGE ESTIMATES AND COST.—THOROUGH-DRAINAGE.— ARTERIAL DRAINAGE.

SUPPLY. —QUALITY.

The supply of water to towns has become latterly a subject of considerable importance. Three points have to be considered,—first, a sufficient supply at high pressure, when it can be obtained within a reasonable expenditure; secondly, the quality; and, thirdly, the cost. The advantages in towns of high pressure are now apparent to all in overcoming fire; fronts of houses and pavements may also be cleaned, and streets watered if the supply be abundant. The highest apartments can be supplied, and even mechanical power can be obtained for many purposes, as grinding coffee, at a reasonable cost. Mr. Glynn says,* "In many parts of London water is supplied at 4d. for 1000 gallons, at a pressure of 150 feet: a gallon of water weighs 10 lbs., so that 1000

^{*} Power of Water.—Weale.

gallons of water falling 150 feet, are equal to 1,500,000 lbs. falling one foot; and if 1500 gallons of water be used in one hour, they are equal to 37,500 lbs. falling one foot in one minute, or somewhat more than a horse's power, which is 33,000; therefore, it may be assumed, that the cost of a horse's power for an hour in such cases, is only 6d."

The number of gallons of water required for the supply of each person, including all collateral uses, has been differently estimated, and varies in almost every town, and even in the same city-London, for instance, when supplied by different companies and under different systems. 44 gallons per head, per diem, were supplied by the several companies of London in 1853, while evidence has been given to show that the actual average consumption for all purposes did not exceed 10 gallons per head, per diem; the remainder having been wasted under an imperfect system of distribution. It is asserted that when the supply is 25 gallons per head, per diem, that 5 gallons of it are used for purposes requiring filtration, 10 gallons for purposes not requiring filtration, and 10 gallons wasted, or two-fifths of the supply. As there must be a considerable loss under even the best system of supply, we may assume, with the Board of Health, that a minimum supply of 75 gallons per house, per diem, or 15 gallons per person, per diem, is necessary.

The following is an abstract of the average number of gallons of water furnished per diem, by different water companies in London, during the year 1853, to each house, including manufactories and public establishments as houses:—

	Gallons.			
	Per House.	Per Person.		
New River Company	193	88-8-5		
East London Water Works	187	87·4-5		
West Middlesex Water Works	204	40.5-5		
Grand Junction Water Works	{ 819 836	{63·4-5 67·1-5		
Southwark and Vauxhall Companies' Houses	175	85		
Ditto average houses, manufactories, public establishments	209	41-4-5		
Chelsea Water Works	227	45.2-2		
Hampstead Water Works	111	22·1-5		
Kent Water Works	270	55		
	2233	446.8-2		
Mean Values	223·8-10	44:3-5		

These quantities have been calculated from the parliamentary returns made in 1854; and if there be any truth in the calculations and returns of the quantities actually consumed per person—said to be 10 gallons—we get the proportion, as 10 is to 34 so is the quantity consumed to the quantity wasted. But, even assuming the quantity consumed to be 20 gallons per head, what an immense loss is here exhibited from want of a suitable system of distribution.

For large towns it is safe to provide for many purposes, besides mere personal or house wants; and it is safer, where it can be done without much cost, to provide for a supply of 40 gallons to each inhabitant, even if this quantity shall not be used or raised. For high pressure, the supply required will generally vary from 15 to 42 gallons, or from 3 to 7 cubic feet to each inhabitant, or an average of about 30 gallons, including the supply to stables, offices, manufactories, and breweries.

The quality of water for drinking, washing, or cooking, is also an important element in selecting a source of supply. Hardness is measured by the number of grains of chalk or carbonate of lime to a gallon of water, each called a degree. The average hardness of spring water is about 26°, that is, 26 grains of carbonate of lime to one gallon of water. Rivers and brooks have an average hardness of 13°, and water derived from surface drainage 5°; hence the great advantage of the latter kinds of water in washing. The average hardness of the London pipe waters is from 10° to 16°. The following report and analyses furnished to me, in 1855, by Professor Sullivan, of the Museum of Irish Industry, Dublin, will show what is generally required on this head:—

"On the annexed page you will find the numerical results of my analyses of the four samples of water which you left with me for examination. From the table you will perceive that the water of the Mattock River appears to be the purest, so far as the nature and the amount of the foreign substances held dissolved in it is concerned. The water of the Boyne comes next in quality to that of the Mattock River, the pump water being in every sense the worst, so far as amount of ingredients can be taken as a test of the quality of a water; in this respect, indeed, it resembles the water of the deep wells of London and elsewhere.

"As the ordinary mode in which the quality of a water, for drinking and for culinary and like purposes, is judged of is, by the comparative amount of organic matter, the total amount of dissolved matter, and its hardness, according to the 'soap test,' I shall give in the following table the numbers representing each of these qualities:—

TABLE showing the number of grains of Organic Matter, and the number of grains of Solid Matter, in an imperial gallon of

Water from	Number of Grains of Organic Matter, per Imperial Gal.	Number of Grains of Solid Matter, per Imperial Gal.	Degree of Hardness according to the Soap Test.	
No. 1. Tullyescar	8·975 grs.	81,175	15 8-10ths.	
" 2. River Mattock .	2 (about)	15,860	9 1-10th.	
" 3. River Boyne	8-250	22,700	14 9-10ths.	
" 4. Burn's Pump	7·100	76,850	84 4-10ths.	

"In order to render this table more instructive, it may be well to subjoin a few of the results obtained from the analyses of the waters of other localities.

Lough Owel	10.225	1.550	6 7-10ths.	

"The quality of a water for drinking purposes depends in a great degree upon the condition in which the organic matter is found, much more than upon its quantity. This is, however, a question outside of the domain of chemistry, and can only be solved by the aid of the microscope. I may, however, venture to remark that the organic matter contained in the water of the Boyne and the Mat-

tock River is of vegetable origin, and would not, so far as I believe, be injurious to health.

"As a general rule, I believe that the water of clear flowing rivers, even though it may contain a large amount of solid matter, and even of organic matter, will be found wholesomer than well water, especially in towns.

"For certain manufacturing purposes, and for culinary purposes, too large an amount of lime is injurious, but I believe that a certain quantity present in water, is not only not injurious, but in my opinion is of the greatest utility, and renders the waters wholesome. I think the rage for extracting pure water containing only one grain of solid matter to the gallon, or thereabouts, for supplying towns, is carried too far. Such water is, no doubt, the best on a hill side; but, I question whether it is equally well adapted for resting in basins, tanks, pipes, &c., with that containing some lime. The River Dodder and Lough Owel waters appear to me the best adapted for city and town supplies. The River Mattock contains rather more than either, but it is decidedly better than the water of either of the canals from which our Dublin supply is drawn.

"Drogheda is rather badly situated for a supply of very soft water, as almost the whole drainage basin of the Boyne is either situated upon limestone, or the feeders of that river rise through the calcareous drift gravel which covers so much of the country. The water of the Boyne appears to be an excellent water for most purposes, and perhaps the difference between it and the Mattock River

Tabular Results of the Special Analyses of Four Samples of Water from the neighbourhood of Drogheda.

may in part be accounted for by its being taken near the banks, or more probably, perhaps, because it was above and close to where some small stream entered.

"The quantity of solid matter in it, however, was not more than I would expect considering the nature of the locality. I did not draw attention in my Report to a point of some importance—namely, the proportion of lime and magnesia existing as carbonates, and as sulphates, and chlorides. The whole

of the lime and magnesia existing as carbonates, and as sulphates, and chlorides, is precipitated by boiling, the water being thus proportionably rendered less hard; lime and magnesia existing as sulphates or chlorides, on the other hand, are not precipitated. This difference is of great consequence in culinary operations, as where boiled water is used, the carbonates of lime and magnesia are not injurious, and if no sulphates or chlorides be present, the water may be soft after boiling. The same observation applies to water applied to washing clothes when boiled. And lastly, sulphate of lime forms one of the worst elements of fur or deposits upon steam boilers."

The saving in soap effected by a reduction of 10 degrees in hardness, is found to be over 50 per cent.

Some of the metropolitan waters analyzed by Dr. Robert Dundas Thomson, F.R.S., were found, in May 1860, much more impure than others, the samples of which had been taken at the beginning of the month, before the impurities conveyed by the rains had contaminated them. The supply afforded by large and small rivers, as in London, in this table, contrasts most unfavourably with that afforded by the drainage of mountain ridges, as at Glasgow and Manchester. The specimens of water from the two latter cities were taken by the instructions of Mr. Bateman, F.R.S., the engineer, from the main pipes during the month. It should be the object of the London Companies to avoid pumping the water in its most impure state, and to store it when in the condition of the greatest purity.

	Total Impurity per gallon.	Organic Impurity per gallon.
Distilled water	Grs., or °. 0.0	Grs., or °. 0-0
Loch Katrine water, new supply to Glasgow	8.16	0.98
Manchester water supply	4.82	0.64
THAMES COMPANIES:—Chelses	17:84	1.48
Southwark	17:08	1.64
Grand Junction	20.72	2.00
West Middlesex	20.08	2-08
Lambeth	20-80	2.40
OTHER COMPANIES:—New River	18-52	1.26
East London	28-64	3-20
Kent	21.68	2.96

The table is read thus:—Loch Katrine water contains in the gallon 3·16 degrees or grains of foreign matter in solution, of which ·96 degrees or grains are of vegetable or animal origin.

Professor Apjohn gives the following analyses of waters furnished to the city of Dublin in 1860. It shows how necessary it is to distinguish the time of taking specimens for analysis, and the previous state of the weather as affecting the foreign matters in the water. The specimens were collected on the 5th and 19th of May, 1860. The quantity operated upon in each instance was an imperial gallon, or 277.273 cubic inches:—

were taken up for analysis.

Organic matter.

It will be observed that the quantities of saline and other ingredients found in specimens of same water collected at the two separate periods above mentioned are materially different: those obtained at the later date (May 19) containing the larger portion of foreign matters. The extent of this variation is very considerable, and it appears to Dr. Apjohn to have been the consequence of a very considerable fall of rain, which took place in the interval between the periods at which the specimens

SOURCES AND GATHERING GROUNDS.

The sources from which a water supply for towns may be derived are lakes, rivers, and streams, springs, wells, and gathering grounds. Of the latter it may be said that, however ably put forward under the auspices of the Board of Health, it is far safer to resort to good river waters than trust to what has been termed, with some satirical truth, "new fangled schemes of pot-piped gathering grounds." Springs and wells afford, at best, but a partial supply unless for villages or manufactories; and we must almost always trust to lakes, rivers, or streams, with sometimes reservoirs, for stowage, for a sufficient supply for large towns. The Croton aqueduct, conveying water with an average of three degrees of hardness, to New York, is perhaps the noblest work for water supply of modern times. The length of the aqueduct is about 44 miles, with a channel inclination of about 15 inches per mile. The receiving reservoir is about two miles higher up the channel than the distributing reservoir, which latter is 115 feet over the level of the sea, and commands the highest buildings of the city. In the driest weather the supply is equal to 28,000,000 gallons. The cost of the work, including the purchase of land and water rights, was 8,575,000 dollars, or £8 per lineal foot nearly. The cost of distributing pipes was 1,800,000 dollars. Latterly we have had the Loch Katrine and Glasgow aqueduct, also a noble work,

^{*} Schramke's Croton Aqueduct, New York.

constructed after this model by Mr. Bateman, notwithstanding the previous supply of that city, or a portion of it, the Gorbals, from gathering grounds at a high level. It is, however, sometimes necessary to make use of such grounds, particularly when

TABLE showing the Quantities of Gathering Ground and Reservoir Room to supply a given population with 15, 30, and 40 gallons of water per head per diem. The reservoir room is calculated to hold 12 inches in depth of rain-fall per mile as a guide for lesser depths. For 4 inches the results are to be divided by 3; and for 6 inches by 2.

Population can be supplied at 15 gallons per head per diem.	Population can be supplied at 80 gallons per head per diem.	Population can be supplied at 40 gallons per head per diem. flanking or lying above glens where an embankment may be easily thrown across, and the supply stored for use, which would otherwise pass quickly off. The table, page 327, gives the areas of reservoirs and gathering grounds according to a collection of one foot in depth from the catchment; it can be easily modified when the storeage or required supply exceeds or falls short of this depth. One acre of gathering ground with a collection of twelve inches of rain-fall from it annually will give a daily supply of five cubic feet per head to twenty-four inhabitants.

The next table will be of use in showing the actual quantities which have been collected, or could have been collected, for storeage. Homersham, Hughes, and Beardmore's books have been consulted in arranging it.

The various methods employed for purification may be classed under three heads: mechanical, by filtering or straining; chemical, or antiseptic media, such as peat and animal charcoal, and precipitation by the use of lime water; and the natural precipitation of impurities when the water is at rest, as well as the purification which takes place from oxidation and neutralization on thorough exposure by the ozone of the atmosphere. This latter plan has, however, been tried, and signally failed. Filter beds may be constructed to have a surface area of one square yard to every 1,000 gallons to be filtered in twenty-four For executed works the proportions vary from 1 in 460 to 1 in 1140. The cost of filtering, in capital, may be said to vary from £30 to £70 for each million of gallons, or 30s. to 70s. annually.

TABLE showing information with reference to size of Reservoirs, Catchment Areas, &c., collected and arranged from various authorities. The first, fifth, and sixth columns contain information with reference to reservoirs and the collecting areas; the second, third, and fourth, show for different districts the whole rain-fall, and the portions or per centage flowing off and available.

Names of Drainage Areas and names of Reservoirs.	Drainage area in aquare miles.	Rain-fall in inches per annum.	Depth of rain in inches per annum flowing off the surface.	Per centage of rain-fall which flows off the surface.	Reservoir room per square mile in millions of cu- bic feet of water.	Contents of Reservoir in mil- tions of enbio feet.

COST.

With reference to cost, the following tables, arranged by us from various sources, will afford information from works executed.

The actual cost of all works for house service varies very much in different towns, and with the quantities supplied, from a general average of 1d. per house per week, to 2d., and from an annual rate of 9d. in the pound to 1s. 6d., and higher. The cost of raising and supplying 1000 gallons from a height of 135 feet in Nottingham, is said to be 3d., and the charge for house service to vary from 5s. to 60s. annually. In Rugby, the average cost per house is 19s. per year, 42d. per week, or an annual charge of 3s. 3d. per year, or 3d. per week per head of the population, and for a bare supply of 13 gallons. In Croydon, for a supply of only 14 gallons per head, the cost of works varied from $1\frac{1}{2}d$. to $2\frac{1}{2}d$. per house per week. The parliamentary returns, showing the number of houses supplied, and cost of supply, by different water companies of London, in 1834, give the following results:-

Cost of house apparatus for private supply from street mains, as averaged by the Board of Health, for first-rate houses, is £3 13s. 2d.; second-rate houses, £2 18s. 6d.; third-rate, £2 3s. 3d.; fourth-rate and cottages, 17s. 5d.; average cost for houses and cottages, £2 8s. 1d.

The actual cost of private works—to take water from mains for the supply of cottages—is shown in the following table:—

Work executed in	NAME OF PLACE.	Mean Expense of Private Works for each Cottage.	Annual Value of each Cottage.

The cost of pumping varies with circumstances; we believe that pumping engines cannot be put down at less than from £60 to £100 per horse power, dependent

on the size of the engine, although the Board of Health adopted a standard of £50 per horse power. For the town of Drogheda we estimated for two engines at £75 per horse power. The following information has been furnished to us respecting the cost of the Waterworks, Cork, by Sir John Benson the engineer, who designed and carried out the works.

CORK WATER WORKS.

			_	
Steam engine 100-horse power.	Direct acting Cornish Engine with three cylindrical flue boilers, includ- ing engine and boiler house, setting boilers, chimnies, &c., &c., per horse power		0	d. 0
Two 50-horse power Tur- bines.	Two Turbines completed with four 11 in. ram pumps on each, including buildings, cisterns, sluices, gates, screens, per horse power	44	0	0
Reservoirs— One of 3,500,000 gallons. One of 568,000 gallons.	One reservoir on a level of 186 feet over weir One reservoir on a level of 360 feet over weir	4,900	0	0
Cost per head.	The inhabitants in 1851, 86,000	0	15	34
	The inhabitants in 1861, 100,000	0	13	0
Valuation standard per pound on the valuation.	City valuation, £112,000	0	11	7
Yearly cost per five inhabitants.	Distribution per house of every five persons	0	5	0
Water supplied.	Quantity supplied, including manufactories, to one person per day	30 gr	allo	n s.

The total estimated cost of engines, including pumps, engine houses, wells, &c., for raising the London sewage, is £70 per horse power, and the annual cost £20 per horse power.*

When coals are 10s. per ton, the cost of an engine

* Main Drainage Report, 1857, p. 29.

exceeding 100-horse power, single acting Cornish, working night and day, will be £10 per horse power; when coals are 15s. per ton, the cost would be £13 per horse power; when coals are 20s. per ton, the cost would be £16 per horse power; when coals are 25s. per ton, the cost would be £19 per horse power. These estimates have been given by Mr. Hughes, and include every expense of coals, wages, oil, tallow, materials for packing, cleaning, &c., but none for interest of capital or depreciation of machinery.*

At Ely the cost of pumping is stated by a writer in the Builder to be as follows:—

To pump one million gallons 140 feet high, the ol	d (engi	ne
consumes—	£	s.	d.
Four tons of coal, at 16s. per ton	8	4	0
Oil, tallow, and packing	0	12	0
Wages	0	8	0
Total cost of pumping one million gallons	4	5	0
The new engine requires—			
Five and a half tons of coal at 16s	4	8	0
Oil, tallow, and packing	1	10	0
Wages	1	2	0
Total cost of pumping one million gallons 140 feet high which is 65 per cent, more money than the old engine requires.	7	0	0

While another writer in the same periodical states, that the cost of pumping 1,000,000 gallons with the old engine was £4 18s. $8\frac{1}{4}d$., and with the new engine, £4 10s. 7d. In the following table, arranged from information in Mr. Hughes' book,† the estimated cost of pumping engines for various works, English and American, is given:—

^{*} Main Drainage Report, 1857, p. 447. † WEALE, London.

ESTIMATED COST OF ENGINES FOR PUMPING, AND OTHER INFORMATION.

Description of Works, and Engineers' estimates, with short description of engines.	Millions of Gallons daily.	Height to be raised in feet.	Millions of Gallons to be raised 1 ft. in 24 hours. In Example 28, pages 39 and 40, we have pointed out the method of calculating the increase of horse power required in raising water through pipes from friction, and also the great increase of this extra head if the velocity increases; the increase being nearly as the square of the velocity. In addition to this, an allowance of horse power must be made for bends, curves, junctions, and other obstructions, for the effects of which see Section XI. The more slowly the water is pumped, the less will the loss be from these causes through the same pipe. It is therefore, so far, advisable to give as large a diameter to the pipes supplying a reservoir from a pumping engine as other aspects of the question, cost, and engine power, will admit.

THICKNESS OF PIPES FOR WATER WORKS.

It is evident that the thickness of a pipe should be at least sufficient to bear the pressure of the atmosphere, and therefore the whole pressure in a pipe is best expressed by a determinate number of pressures, each equal to that of a column of water 33 feet high. If n be the number of such pressures, or the number of units each equal 33 feet high, d the diameter of the pipe in inches, and t the thickness, also in inches, we shall have for

```
(A).  \begin{cases} 1. & \text{Iron pipes, plate } ... & t = .0009 \, nd + .18. \\ 2. & \text{Iron pipes cast horizontally} & t = .0024 \, nd + .83. \\ 3. & \text{Iron pipes cast vertically} & t = .0016 \, nd + .82. \\ 4. & \text{Copper pipes, plate } ... & t = .0015 \, nd + .16. \\ 5. & \text{Lead pipes } ... & t = .0024 \, nd + .19. \\ 6. & \text{Zinc pipes } ... & t = .0051 \, nd + .16. \\ 7. & \text{Artificial stone } ... & t = .0054 \, nd + 1.60. \end{cases}
```

For cast-iron pipes the engineer of the Paris water works, M. Dupuis, adopted in his practice a formula which is equivalent to

(B.)
$$t = .0016 nd + .32 + .013 d$$

in the foregoing measures. This formula may also be expressed as follows:—

(C.)
$$t = (.0016n + .013) d + .32$$
.

If d be 12 inches, and n = 9, corresponding to a pressure of 297 feet, we shall find from the last equation, $t = (0.0144 + 0.013) \times 12 + 0.0336 + 0.0336 + 0.032 = 0.0536$ inch. All pipes should however be proved with ten atmospheres, or 330 feet, and in practically applying the above formulæ in equation (A), for finding the thickness of pipes, the value of n should always have 10 added to it. Hence, applying formula (A), No. 3, to our example, we get $t = 0.016 \times 19 \times 12 + 0.032 = 0.0336$ inch, which is the same practically as found from equation (C).

SEWERAGE COST.

As for water works, the minimum rain-fall of a district should be calculated upon, so the maximum fall must be considered in sewerage and drainage. We have already shown, page 305, that for a population of 80 persons per statute acre, and a discharge of two-fifths of an inch in eight hours, sewers should be calculated to discharge about 3½ cubic feet per minute, the rain supply being about seven times the house supply, or sewage, including house water supply. Instances are quoted in which the discharge, after a heavy rain-fall, amounted to

20½ cubic feet per minute per acre, as in the Savoystreet sewer, which of course was principally surface water, as the sewage of 80 persons at 7 cubic feet per person, one-half of which, if discharged in

eight hours, would only be $\frac{80 \times 7}{8 \times 2} = 35$ cubic feet

per hour, or $\frac{35}{60} = .59$ feet nearly per minute, which

is only about the thirty-third part of 20½ feet. other words, the storm waters were thirty-three times the amount of house sewage. It would be waste to provide drainage for so much surface water considered in itself, where it can be passed off from the surface channels. But sewage is not water, and it is essential, in the greater number of cases, that sewers should be flushed occasionally. It is absurd to calculate the size of sewers, as if the sewage matter were thoroughly diluted or passed off like water. In fact, the sewage in part lies at the bottom of the sewer, or is deposited there in nine cases out of ten, while the house supply of water passes on and escapes over it, removing only diluted and detached portions. It is, therefore, of importance, where artificial flushing and cleansing out are not provided, that storm waters should occasionally pass through and flush a system of sewers, particularly the main or arterial lines. An engineer must be guided, in calculating the dimensions, &c., of main sewers, by the circumstances of each case. The inclinations to be obtained, the form of the bottom or invert, the rain-fall, the amount of sewage which will not affect the size to any considerable

extent, the material and the cost consistent with permanency.

The discharging power of a water channel is more than doubled by increasing its dimensions by onethird; and it is increased in the proportion of 5.7 to 1 by doubling the dimensions. By giving four times the fall, the same channel will only double the discharge. Now a pipe 2 feet in diameter with a fall of 1 in 200, would discharge fully 1000 cubic feet of water flowing full with a velocity of 5.4 feet per second: at 31 cubic feet per minute per acre, for a population of 80 to the acre, the thoroughly diluted sewage of 280 acres would be passed off by one such pipe; that is, the sewage from 20,400 persons, on 280 acres, and also two-fifths of an inch of rain falling for eight hours, can be conveyed by a 2 feet pipe, with a fall of 1 in 200. But as this rain supply is about seven times the house supply, passing 24 feet off per person in eight hours, made up of fæces and used-up water supply. It is apparent that such a pipe would convey about eight times the sewage alone of the district, if flowing as water; but, under any circumstances, would be abundantly large for the duty, even when assuming the whole quantity to pass in at the upper end. For a fall of 1 in 800, two such pipes would be required, or one pipe 32 inches in diameter; for a fall of 1 in 3200, four 2 feet pipes would be required, or one pipe 3 feet 6 inches.

House drains should not be less than 6 inches in diameter, and should have facilities for being cleaned, either by using half-flange joints, or by having a

moveable upper segment. The inclination for these drains should be uniform, but the amount is not so important as some appear to think, if proper provision be made for cleaning. Where flushing is used, cast-iron pipes are the best, but they are also the most expensive. House drains of brick with a ville bottom covered with flags or bricks are perhaps the best, as the capacity can be considerably augmented by adding to the height of the sides, and they can be at all times easily opened and cleaned. If inclinations from 1 in 50 to 1 in 20 can be had, so much the better. The following items as to cost have been selected from the Builder:—

Total lengths.	Average depths.	Sizes of sewers.	Thick- nesses.	Cost per foot lineal.

15 ,,	9d.	,,	5 feet deep.
18 "	11 <i>d</i> .	**	5 feet deep.

2d. per foot lineal for relaying pitching; 4d. for macadamized roads; and 6d. for pavements.

The author has constructed a large quantity of main sewers, from 18 inches to 2 feet and 2 feet 6 inches wide, and 4 feet 6 inches high; the side walls built with rubble masonry, 9-inch segment inverts laid with 41-inch courses in cement: the top sometimes flagged, when flags of sufficient length could be procured, and sometimes arched with rough rubble arches. The invert was laid on, well bedded, well rammed, rubble to prevent subsidence, and preserve the bottom inclination uniform. The cost, at an average depth of about 9 feet, was 9s. per running foot, the side walls being about 18 inches thick. Upright side walls, where rubble is cheap, have many advantages in giving a considerable increase of capacity for a small outlay. The tenement and house drains were of earthenware pipes. Cast-iron gully grates and traps, weighing 3 cwt., cost 30s. each; the grate fastened by a wrought-iron chain.

The following regulations have been laid down for Cambridge and Carlisle:—

STIPULATIONS FOR CAMBRIDGE DRAINAGE.

- "Water from the rear of premises should not be conveyed to the front under the basement floor.
- "Rain-water from the roofs should not be conveyed into the basement, but conducted into the sewer by shallow drains.

- "Cast-iron pipes may be used for basement drains in some instances.
- "The scullery sink should be kept as high as possible, and approached by a step. A flap trap should be fixed between the sink and sewer.
- "There should be no water-closet on the basement floor; if it cannot be arranged elsewhere, the soil-pipe should have a flap trap, or similar contrivance, to prevent the influx of sewage water."

FOR CARLISLE DRAINAGE.

- "STIPULATION 1.—If water-closets are to be generally used, the description of such to be sanctioned by the Board, the same to be fixed to the satisfaction of the Surveyor.
- "2.—All down-spouts to be connected with the sewers where it may be proper to connect the same; in all cases where they are not connected with the sewer they are to be connected with the channel.
- " 3.—All stench traps to be similar to samples furnished by the Surveyor, or others approved by him, and properly fixed to his satisfaction.
- " 4.—All sewers to water-closets not to be less than six inches diameter.
- " 5.—All sewers to yards, stables, kitchens, and sculleries, not to be less than four inches diameter.
- "6.—In every case the whole of the fall to be made available from the junction with the main sewer to the end of the private drain, that is to say, only one inclination to be used from the junction with the public sewer to the end of the private drain; and all branches from the private drain to sinks, water-closets, &c., to have one inclination from the junction of such drain. None of the above instructions to be departed from without the express sanction of the Surveyor.
- "7.—In no case must a private drain be put in with a less fall than one in fifty, without the sanction of the Surveyor.
- "8.—No pipes, water-closets, stench traps, gullies, kitchen sinks, bends, junction or tapering pipes, to be used without being approved by the Surveyor.
- "9.—All ash pits and dung depôts to be raised to the level of the adjoining ground, to be properly paved and drained as the Surveyor may direct.

"10.—All buildings, outhouses, &c., to be properly spouted, and the water conveyed into the sewers where approved of by the Surveyor."

THOROUGH LAND DRAINAGE.

The following instructions and general specifications, have been prepared by the Commissioners of Public Works in Ireland, for the use of the District Inspectors, and persons reporting on thoroughdrainage. The drains are made in general parallel, and to suit the fall of the ground. The depths must alter in order that the bottoms should have an uninterrupted fall, and may vary from 2 feet to 4 feet 6 inches in practice, averaging, say about 3 feet 6 inches, but dependent on circumstances. The portions printed in italics are from specifications prepared by officers of the Board, and are varied according to each particular case:—

GENERAL OBSERVATIONS.

- "No drainage works should be undertaken until it has been clearly ascertained that the surface level of the maximum floods in the main drain can be discharged at a level that will admit of the submain drains venting the waters from the lowest point of the lands proposed to be thorough-drained, at a level sufficiently below the surface of such land, that the highest floods shall not prevent the free discharge of such submain.
- "When sufficient out-fall can be obtained, no open main drain should be of a less depth than five feet, and in all cases a greater depth is desirable, in order to insure a permanent and efficient drainage, and at the same time to prevent cattle, &c., from crossing.
- "As it has been found by practical experiments on different varieties of soils, that deep drains, say from four to five feet deep, are more effective than shallow ones: they should always be estimated for, when the open main drains admit of their being

cut to that depth, or when, by a moderate outlay per acre, the main drains can be cut to a sufficient depth; the distance between the parallel drains must necessarily vary with the texture of the soil,—forty feet may be taken as a general rule.

OPEN MAIN DRAINS.

- "Main drains should have gradients of such inclination, and be sunk to a depth that will admit of the above stipulations, as to the discharge of the submain drains being carried out. They should have such width at bottom and side slopes as may be necessary; and be free of sharp angles, projecting stones, and other impediments to the quick discharge of the waters.
- "The spoil or material raised in sinking and improving the drains, where not available for filling up useless holes or drains, should be removed to a proper distance from the edge of the main drains, and dressed off in a workmanlike manner.
- "The abutments and piers of such bridges as have sufficient breadth of water-way, should, if necessary, be carefully underpinned; and those bridges which are insufficient to discharge floods, should be taken down and rebuilt of suitable dimensions.

COVERED MAIN DRAINS.

"Whenever, from the nature of the lands, the extent of the district under drainage, and the quantity of water to be voided, it may be necessary to form covered main drains to receive the water discharged from the submains, their dimensions must be proportional to the amount of water to be voided, well flagged or paved at bottom, the sides built of stone or brick, and covered with a flag or arch at top.

SUBMAINS.

"The submains to be of such depth and width at top and bottom as may be necessary. The fall in each to be as great as the above-described main drainage of the district will allow, and not to be allowed to run beyond a suitable length without discharging itself into a covered or open main drain.

THE MINOR DRAINS

"To be of such depth, width at top and bottom, and at such distance apart, as will secure the perfect drainage of the land, to be run in a straight direction parallel to each other, directly up and down the declivity, unless where the declivity happens to be very steep, and then to be carried across the fall at such an angle as to secure a free discharge for the water. The fall in each minor drain to be as great as the main drainage and submain drainage, previously described, will admit.

"In filling in the stones, great care should be taken that the bottom of the drain be clean, and that no clay or dirt be put in with them; a sod, grass side down, or a few inches of tough clay, to be placed on the surface of the stones, and trodden firmly. The drain should then be filled up with the stuff previously shovelled out, observing to keep the active soil for the top. The putting in of the stones to be commenced at the highest part or head of the drain.

"In using draining pipes or other tiles, care should be taken that they be laid firmly on the bottom for their entire length, so as to prevent them being deranged by the filling of the drain, and that the points be fitted as closely together as possible.

"In cases of unfavourable ground, caused by running sand or otherwise, whereby the level of the conduit might be deranged, collared pipe tiles offer considerable advantages in the way of remedy.

"When gripes may be necessary on the sides of farm roads, they should be on the field side of the fences."

SPECIFICATION FOR MAIN DRAINAGE.

OPEN MAIN DRAINS.

"The deepening and improving of the main drain, No. ——, is to be commenced at the point —— on the accompanying map, and from thence a gradient carried up to the point ——, having an inclination of at least —— feet per statute mile, and sunk to the depth of —— feet. It shall be —— feet wide at bottom, and the side slopes shall average —— at least, unless in rock cutting, when the side slopes may be diminished to six inches to one foot; all sharp angles, projecting stones, and other impediments to the

free discharge of the water, must be carefully removed. The spoil or material raised in sinking and improving the drain, when not immediately used for top-dressing the adjoining lands, or for filling useless holes or drains, is to be removed to a distance of —— feet from the edge of the main drain, and dressed off in a workmanlike manner.

"The bridge marked at the point —— on the accompanying map to be ——.

"The whole to be executed in a proper and workmanlike manner, and the works to be maintained in good order for so long as any interest shall be payable for the money advanced on account of its execution."

SPECIFICATION FOR THOROUGH-DRAINAGE (WITH TILES).

COVERED MAIN DRAINS.

"These shall be cut fifty-four inches deep, thirty-six inches wide at top, twenty-four inches wide at bottom; the materials used in them shall be double row of three-inch pipe tiles.

"The side walls shall be —— inches in height, —— inches thick, and well —— at bottom. They shall be covered with a flag not less than —— in thickness.

SUBMAINS.

"These shall be cut fifty inches deep, thirty inches wide at top, sighteen inches wide at bottom. They shall be carried along the low side of the fields, or portions of land to be drained, at a distance from the fence of fifteen feet, and through natural hollows where necessary. No submain to be allowed to run beyond a length of two hundred yards without discharging itself into a covered or open main drain.

MINOR DRAINS.

"These shall be cut forty-eight inches deep, sixteen inches wide at top, five inches wide at bottom, and at a distance of forty feet apart. They shall be run in a straight direction, parallel to each other, directly up and down the declivity (when possible). No minor drain to be allowed to run beyond a length of two hundred yards without discharging itself into a submain.

FILLING IN.

"All the drains (or a large number of them) having been opened and cut in a workmanlike manner, and it being ascertained that no water is standing in any of them, the filling in may be commenced.

MINOR DRAINS.

"Into each minor drain shall be put pipe tiles twelve inches in length, one-and-a-half inch in the ope, for one hundred yards, commencing from the upper end of the drain, and pipe tiles twelve inches in length, one-and-three-quarter inch in the ope, in continuation from thence to the submains.

SUBMATNS.

"Into each submain shall be put pipe tiles twelve inches in length, two inches in the ope, for one hundred yards, commencing from the upper end of the drain, and pipe tiles twelve inches in length, three inches in the ope, in continuation to the end or point where they discharge themselves.

GENERAL RULES.

- "All tiles to be of good sound material, and well burned. The tiles shall be laid firmly on the bottoms of the drains for their entire length; the joints fitted as closely as possible, they shall be carefully covered with a thin grassy sod or screen. The stuff previously taken out of the drains shall then be returned, observing to keep the active soil uppermost.
- "The mouths of the covered main or submain drains shall be built about with solid masonry set in mortar, carried up with the same slope as the sides of the open main drain, into which they discharge themselves.
- "Before laying the tiles, great care must be taken that the bottom of the drains be clean. The putting in of the tiles to be commenced at the highest point or head of the drains.
- "In case of an entire field being thorough-drained, a drain shall be cut at the top of it, parallel to the fence, and running at a distance from it equal to one-half of the distance between each of the minor drains, into one or more of which (as may be necessary) it shall discharge itself. The remainder of the minor drains to be discontinued at a distance from this drain equal to

one-half the entire distance between each of the minor drains; this drain to be of the same dimensions, and filled with the same materials, and in like manner, as the above described.

- "No open drain shall run into a closed one.
- "In passing through unfavourable ground, caused by running sand or otherwise, whereby the level of the conduit might be deranged, and where pipe tiles are the materials used for forming the conduit, collars must be used, so as to connect the ends of the tiles, and they must be fitted as closely as possible.
- "Soles must, in all cases, be used when laying single D tiles, and they must be so laid that the ends of the tiles shall rest equally on them; when inverted D tiles are used, they shall also be connected from end to end by placing one-half of the upper tiles on one-half of the adjoining tiles below them.
- "The whole to be executed in a proper and workmanlike manner; and the work to be maintained in like good order as when approved of at its completion, for so long as any interest shall be payable for the money advanced on account of its execution." [Collars for up to 4-inch pipes can be had at the Florence Court Tilery.]

SPECIFICATION FOR THOROUGH-DRAINAGE (WITH BROKEN STONES).

COVERED MAIN DRAINS.

- "These shall be cut forty-two inches deep, thirty inches wide at top, twenty-four inches wide at bottom; the materials used in them shall be ——.
- "The side walls in them shall be twelve inches in height, six inches thick, and well —— at bottom. They shall be covered with ——.

SUBMAINS.

"These shall be cut forty-two inches deep, eighteen inches wide at top, fourteen inches wide at bottom. They shall be carried along the low side of the fields, or portions of land to be drained, at a distance from the fences of thirteen feet, and through natural hollows, where necessary. No submain to be allowed to run beyond the length of one hundred and fifty yards, without discharging itself into a covered or open main drain.

MINOR DRAINS.

"These shall be cut thirty-six inches deep, fifteen inches wide at top, four inches wide at bottom, and at a distance of twenty-six feet apart. They shall be run in a straight direction, parallel to each other, directly up and down the declivity (when possible). No minor drain to be allowed to run beyond a length of two hundred yards without discharging itself into a submain.

FILLING IN.

"All the drains (or a large number of them) having been opened and cut in a workmanlike manner, and it being ascertained that no water is standing in any of them, the filling in may be commenced.

MINOR DRAINS.

"Into each minor drain shall be put ten inches of broken stones in depth, the stones having been broken to a size not exceeding two-and-a-half inches in diameter. Great care should be taken that the bottom of the drain be clean, and that no clay or dirt be put in along with the stones; a sod (or clay, as may be convenient) three inches thick shall be placed carefully on top, and the whole trampled upon or rammed hard. The drain shall then be filled up with the stuff previously shovelled out, observing to keep the active soil for covering the top. The putting in of the stones shall invariably be commenced at the highest part or head of the drain.

FILLING IN SUBMAINS.

"In each submain a conduit shall be formed of six inches in height, four inches wide, and the filling in completed as above described.

GENERAL RULES.

- "The mouths of the covered main or submain drains shall be built about with solid masonry set in mortar, carried up with the same slope as the sides of the open main drain into which they discharge themselves.
- "Before filling in the stones, great care must be taken that the bottom of the drains be clean, and that no clay or dirt be put in

A A

along with them. The putting in of the stones to be commenced at the highest part or head of the drains.

"In case of an entire field being thorough-drained, a drain shall be cut at the top of it, parallel to the fence, and running at a distance from it equal to one-half the distance between each of the minor drains, into one or more of which (as may be necessary) it shall discharge itself. The remainder of the minor drains to be discontinued at a distance from this drain, equal to one-half the entire distance between each of the minor drains; this drain to be of the same dimensions, to be filled with the same material, and in like manner, as the above described.

" No open drain shall run into a closed one.

"The whole to be executed in a proper and workmanlike manner, and the work to be maintained in like good order as when approved of at its completion, for so long as any interest shall be payable for the money advanced on account of its execution."

One of the officers of the Commissioners of Public Works, Ireland, the Inspector of Drainage for Roscommon, a gentleman residing in that county, writes to me as follows, with reference to tile and broken stone drains on the carboniferous formation:—

"With respect to tile drainage my experience has not been very extensive, as the proprietors of the district, with scarcely any exception, give a decided preference to broken stones; but from what I have seen, I am very much inclined to prefer good well-burnt pipes to any other draining material, provided that collars be used, but not otherwise. As to the best diameters, I have found the 1½ collared pipes of the Clonbrock Tile Works (now closed) very satisfactory; but when the length of minor drains exceeded 100 yards, I should like an increase to 1½ or 1½. For submains (say 150 or 180 yards long) I have recommended pipes of 2 inches, 2½, and 3 inches in succession, all of which were to be had

with collars: if 4-inch pipes were to be had with collars, I should have recommended longer submains. The larger-sized pipes are not provided with collars in our present tileries, and on this account I generally put a note on the margin of the printed form, suggesting that a stone duct of the ordinary size of submain, say 6 inches in height and 4 inches wide, be substituted for the tile filling.

"I decidedly prefer an open duct to broken stone filling; and in nine-tenths of my own drainage I have made the minor drains on the same plan as the submain, with an open stone conduit; the only difference being, that the minor drains are a few inches shallower, with a smaller duct. The increase of expense is a mere trifle, and when the substratum (as very frequently occurs here) is a fine calcareous gravel, containing 40 to 60 per cent. carbonate of lime, the additional spoil is a very cheap fertilizer for the land.

"With respect to depths and distances apart, the two most commonly used in my specification are 3½ feet deep, 33 feet apart,—and 4 feet deep, 42 feet apart. These arrangements will not suit all cases, and I vary accordingly. Thus, in one case of exceedingly retentive land of peculiar texture, 4 feet drains, 27 feet apart, produced the required result, while in another, 3½ feet drains, 66 feet apart, effected all that was required. In the latter case there was a mixed soil, which might be described as "half wet;" yet the water lingered sufficiently long to make the land unsound for sheep, and greatly to injure the crops in quality as well as quantity."

Mr. Josiah Parkes says, in 1843:-- "Experiment

and experience have rapidly induced the adoption of a system of parallel drains, considerably deeper, and less frequent, than those commonly advocated by professed drainers, or in general use. I gave several instances of this practice in Kent in the Report of last year, 1843, already alluded to, and it is rapidly extending. Mr. Hammond stated to you that he drained 'stiff clays 2 feet deep, and 24 feet between the drains, at £3 4s. 3d. per acre, and porous soils 3 feet deep, 33½ feet asunder, at £2 5s. 2d. per acre.' I now find him continuing his drainage at 4 feet deep, wherever he can obtain the outfall, from a conviction founded on the experience of a cautious progressive practice as to the depth and distance, that depth consists with economy of outlay as well as with superior effect. He has found 4-feet drains to be efficient, at 50 feet asunder, in soils of varied texture-not uniform clays-and executes them at a cost of about £2 5s. per acre, being 18s. 4d. for 871 pipes, and £1 6s. 6d. for 53 rods of digging. Communications have been recently made to me by several respectable Kentish farmers, of the satisfactory performance of drains deeply laid in the Weald clays, at distances ranging from 30 to 40 feet, but I have not had the opportunity of personally inspecting these drainages.

"The following little table shows the actual and respective cost of the above three cases of underdraining, calculated on the effects really produced, that is, on the masses of earth effectively relieved of their surplus water at an equal expense. I conceive this to be the true expression of the work

done, as a mere statement of the cost of drainage per acre of surface conveys but an imperfect, indeed a very erroneous, idea of the substantive and useful expenditure on any particular system. This will be apparent on reference to the two last columns of the table, which give the cost in cubic yards and square yards of soil drained for one penny, at the above mentioned prices, depths, and distances.

Depth of drains, in feet.	Distance between the drains, in feet.	Mass of soil drained per acre, in cubic yards.	Mass of soil drained for one penny, in cubic yards.	Surface of soil drained for one penny, in square - yards.
2	·24	32264	4·1	、6•27
8	88 <u>1</u>	4840	8-98	8.93
4	50	6458	12:00	[,] 8-96

"I may here observe, that Mr. Hammond, when draining tenacious clays, chooses the month of February for the work, when he lays his pipes (just covering them with clay to prevent crumbs from getting in), and leaves the trenches open through March, if it be drying weather, by which means he finds the cracking of the soil much accelerated, and the complete action of the drains advanced a full season. The process of cracking may, doubtless, be hastened both by a choice of the period of the year in which drains are made, and by such a management of the surface as to expose it to the full force of atmospheric evaporation."

With reference to drains, we have known a case in the Queen's County in which inch pipes had to be taken up, and pipes of 2½-inch bore substituted.

The drains were 40 feet apart, and 4 feet deep, and the pipes had collars. The minor drains should discharge into submains at convenient distances, say 100 yards, on flat grounds. Small pipes will choke unless the velocity in them be sufficient to carry off deposits, and the diameters should vary according to the inclinations of the ground, and distance apart of the drains.

Mr. Mechi, in 1844, lays down the following rules:—

"1st.—That it is not the size or form of the drains that regulate perfect drainage; but the depth at which they are placed. The depth also governs the distances at which the drains should be cut according to the quality of the soil.

"2nd.—The pipes of 1-inch bore, without stones, are amply sufficient, placed at 4 feet deep and 30 feet wide in dense soils, and the same depth and 50 feet wide in mixed soils.

"3rd.—The deep drains receive more water than shallow ones, and consequently lay dry a greater extent of ground.

"4th.—The deep drains begin and end running sooner than shallow ones, and carry off more water in a given time.

"5th.—That where shallow drains are made and deep ones cut below them, the shallow ones no longer act, all the water passing to the deeper drains.

"6th.—That when round stones are used as well as pipes, the latter should always be placed at the bottom, as I find, practically, water flows more quickly through pipes than amongst stones.

"Before persons begin draining, I would recommend their perusing attentively the facts developed by Mr. Parkes, at pages 39 and 40, and my remarks at page 36 of Letters on Agricultural Improvements.

"Pipes made to socket into each other (by Ford's

Patent Socketing Machine) are best adapted to loose or mixed soils."

Pipes laid, however, too near the surface, are frequently choked with the roots of plants. The principal advantage of submains alongside open mains is, that the mouths of the minor drains should not be choked from vegetation, and that the water from them, flowing into and taken up by this submain, may be discharged by a few apertures only, and thereby keep themselves open, or as much so as the nature of the case will admit. The foregoing tables show the cost per statute acre, in Ireland, of thorough-drainage, which must vary with circumstances, locality, and the value of labour.

The average cost per statute acre for Sir Richard O'Donnell's Gold Medal, was £3 5s. 7d., and £4 13s. 10d. for the Society's Gold Medal; average of both, £4 per statute acre nearly.

The average number of acres now annually improved in Ireland, is about 5530, at an average cost per acre of £4 17s.

In Ireland, thorough-drainage is almost generally carried out by loan, under the Commissioners of Public Works, and there is no branch of the public service has given more satisfaction to owners of property. The works are, we believe, always executed within the estimates, and the owner having the expenditure in his own hands, can satisfy himself of its proper application. No loans are made unless where immediately, or prospectively, a return of 61 per cent. is estimated on the expenditure, a rent charge for this amount being made for 22 years.

ARTERIAL DRAINAGE.

The effect of thorough-drainage on the arterial channels of a district, is to discharge the rain-fall into the main channels in a shorter time than before, particularly during wet seasons. This frequently causes floods to rise higher as well as more rapidly. During dry seasons the supply is less, and so far, when it is limited, an injury is done to the adjacent districts requiring it for use. The effect of obstructions in the main channel is to impound the upland water, sometimes made available for water power or navigation purposes, but in general, to the iniury of the drainage of adjacent lands, and the regimen of the river, particularly in flat districts. The arterial drainage in Ireland has effected a vast amount of good, but up to 1853 the estimates appear to have been usually doubled; the estimates for eleven of these works being £124,647, and the expenditure, £293,532. The average cost per acre, on the land improved by these projects, varied from £1 19s. 8d. to £5 17s. 7d., the average of the eleven districts being £4 3s., which is about the average for thorough-drainage.*

The following table affords valuable information of the cost of arterial drainage works in Ireland: it is extracted from the Report of the Commissioners of Inquiry, presented to the House of Commons June 16th, 1853.

^{*} See Parliamentary Report, by Sir Richard Griffith, Sir W. Cubitt, and Jas. M. Rendel, June 16th, 1853.

8	,,	266,420	21,033	8	9	4
84	**	1,114,067	88,501	8	17	7

The last line gives the general average, and shows that in these 84 districts, about 1 acre in 13 is the average of flooded lands to the catchment area, or 8 per cent. nearly.

SECTION XIV

THE AND HORSE POWER.—FRICTION BRAKE, OR DYNAMOMETER.—CALCULATION OF THE EFFECTIVE POWER OF
WATER WHEELS.—OVERSHOT, UNDERSHOT, AND BREAST
VERTICAL WHEELS.—HORIZONTAL WHEELS AND TURBINES.
—HYDRAULIC RAM.—WATER ENGINE.

Taking the representative of a horse's power at 33,000 foot-pounds* or 33,000 lbs. raised one foot

• 16,500 foot-pounds, or one half of the above, is much nearer the average power of a horse, working for 10 hours only, as the work is ordinarily done through the country; 33,000 lbs. raised one foot per minute, is equivalent to 884 tons, nearly, raised one foot in an hour. Therefore, a river discharging 884 tons, over a fall one foot high in an hour, or 884 tons, over a fall 24 feet high

high in one minute, the theoretical horse-power of an overfall is expressed by the fall in feet, multiplied by the discharge in cubic feet per minute, the product multiplied by 62½ (the weight in lbs., nearly, of a cubic foot of water), and divided by 33,000. The following table gives the weight in air of a cubic foot of pure water at different temperatures, Fahrenheit's thermometer.

WEIGHT OF A CUBIC FOOT OF WATER.

The weight of 36 cubic feet of water is one ton, nearly.

Tempe- rature, in degrees.	Weight of a cubic foot of water. Pounds Avoirdupois.	Tempe- rature, in degrees.	Weight of a cubic foot of water. Pounds Avoirdupois.	Tempe- rature, in degrees.	Weight of a cubic foot of water. Pounds Avoirdupois.

The effective power of a fall depends on the nature,

in 24 hours, has also a horse power. The drainage of 10 square miles, with an average collection of 12 inches annually of rain in depth, will give an annual unceasing one-horse power for each foot of fall in a receiving channel; or five square miles will give the same result, if the collection amounts to 24 inches in depth. The collection of 10 square miles, one foot deep, yearly, is nearly equal to the delivery of 530 cubic feet per minute, for the same period.

proportions, and construction of the wheel or machine, and also upon the manner in which the theoretical power is applied. When the velocity of a stream acting on a wheel only is known, the theoretical head, h, due to it is found in feet from the formula $h = 0.0155 v^2$, v being the volocity in feet per second.

In order to gauge the quantity of water applied to a wheel, and thereby determine with accuracy its effective power, the water used must be passed through a notch, orifice, or over a weir, the coefficients for which had been previously ascertained from experiment. Greater accuracy can be obtained from gaugings through thin plates, or planks having the down-stream arrises chamfered, than with any other form of orifice or notch; and when it can be effected, the channel above should be sufficiently enlarged to prevent the effects of an approaching current. We have already in the body of this work dwelt in detail on the various formulæ required for gauging under different circumstances. The accuracy of the results showing the effective powers of wheels depends in the first place, on the accuracy of the gaugings or estimates of the quantity of water used, and next on the fall employed.

FRICTION BRAKE, OR DYNAMOMETER.

The power applied to a revolving shaft through a water wheel of any construction, is the weight of water multiplied by the fall. It is evident that the portion of this power available to turn a shaft and machinery, or the effective power, must depend on

the construction of the wheel, as a portion of the theoretical power is lost mechanically, in applying it; in changes of direction, friction, eddies, and discharging currents. The greater the effective power conveyed to a shaft, the greater becomes the power of the wheel, or medium through which the original power is transmitted. The mechanical effect produced by a revolving shaft is best measured by a friction brake, the principle of which is as follows. In diagram 1, Fig. 44, let the friction pulley AA be

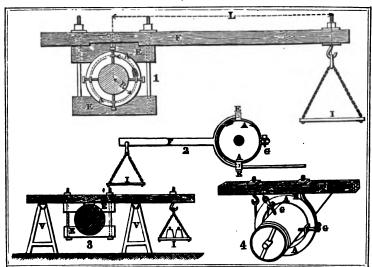

FIG. 44.
FRICTION BRAKES, OR DYNAMOMETERS.

firmly fixed to the revolving shaft or axis of the wheel; E and E, two wooden clamps grasping the friction pully by means of the screw bolts, delineated, which can be tightened on the axis, and also to the arm F, by means of suitable nuts. The more tightly the bolts are screwed, the greater will be the friction between the friction pulley AA, and the clamping pieces EE. If, while the axis and friction pulley AA, are revolving in the direction indicated by the arrow, a weight be applied in the scale at 1, so that the arm r shall not be carried round, but remain fixed; it is clear that the work done by the revolving shaft in one revolution, will be measured by the circumference of the friction pulley, multiplied by the friction due to the pressure on it, or by its equivalent, the weight in the scale 1, multiplied by the circumference of a circle whose radius is L, or by $2 L \times 3.14159 \times w$, in which expression w is the weight in lbs. in the scale I. If n be the number of revolutions in a given time, say one minute, we shall therefore have the useful effect of the wheel on the shaft in footpounds per minute, equal to

$$2 L \times 3.14159 \times w \times n$$
.

We have also the power of the water acting on the wheel, equal to

$$h \times D \times 62.37$$
,

in which h is the head and p the discharge in cubic feet per minute; therefore, we shall have for the ratio of the effect to the power the expression

$$\frac{2 L \times 3.14159 \times w \times n}{h \times D \times 62.37}$$

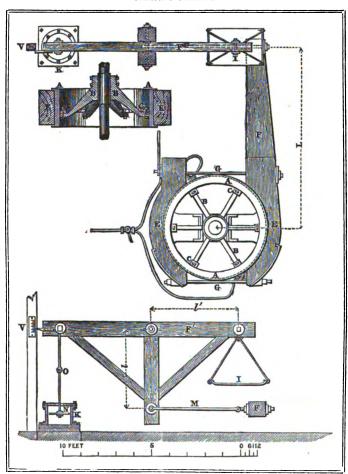

If the revolving shaft be horizontal, the weight of the arm \mathbf{r} , acting at its centre of gravity and reduced to the length \mathbf{L} , where the weight \mathbf{w} is suspended, will have to be included in the weight \mathbf{w} . If the weight \mathbf{w} be suspended at the end of a connexion of levers, or other mechanical powers, the length \mathbf{L} will have to be determined accordingly. Diagram 2, Fig. 44,

shows the Armstrong-brake; Diagram 3, the common form; and Diagram 4, Egen's brake.

Fig. 45, is a general representation of the brake

Fig. 45.

DYNAMOMETER FOR DETERMINING THE USEFUL EFFECT OF THE TREMONT TURBINE.

used by Francis, in the Lowell experiments. The length of the arm of the brake L, was 9.745 feet; the length of the vertical arm l of the bell crank 4.5

feet; and the length of the horizontal arm 7 5 feet. The following detailed description is by Francis:—

"The Friction Pulley A is of cast-iron, 5.5 feet in diameter, two feet wide on the face, and three inches thick. It is attached to the vertical shaft by the spider B, the hub of which occupies the place on the shaft intended for the bevel gear.

"The friction pulley has, cast on its interior circumference, six lugs, cc, corresponding to the six arms of the spider. The bolt holes in the ends of the arms are slightly elongated in the direction of the radius, for the purpose of allowing the friction pulley to expand a little as it becomes heated, without throwing much strain upon the spider. When the spider and friction pulley are at the same temperature, the ends of the arms are in contact with the friction pulley. The friction pulley was made of great thickness for two reasons. When the pulley is heated, the arms cease to be in contact with the interior circumference of the pulley, consequently they would not prevent the pressure of the brake from altering the form of the pulley. This renders great stiffness necessary in the pulley itself. Again, it is found that a heavy friction pulley insures more regularity in the motion, operating, in fact, as a fly-wheel, in equalizing small irregularities.

"The brakes E and F are of maple wood; the two parts are drawn together by the wrought-iron bolts c c, which are two inches square.

"The bell crank \mathbf{r}' , carries at one end the scale \mathbf{I} , and at the other the piston of the hydraulic regulator \mathbf{K} ; this end carries also the pointer \mathbf{L} , which indicates

the level of the horizontal arm. The vertical arm is connected with the brake r, by the link m.

"The hydraulic regulator K, shown in the figures, is a very important addition to the Prony dynamometer, first suggested to the author by Mr. Boyden, in 1844. Its office is to control and modify the violent shocks and irregularities, which usually occur in the action of this valuable instrument, and are the cause of some uncertainty in its indications.

"The hydraulic regulator used in these experiments, consisted of the cast-iron cylinder k, about 1.5 feet in diameter, with a bottom of plank, which was strongly bolted to the capping stone of the wheel pit, as represented in figure 1. In this cylinder, moves the piston N, formed of plate-iron 0.5 inches thick, which is connected with the horizontal arm of the bell crank by the piston rod o. The circumference of the piston is rounded off, and its diameter is about 18 inch less than the diameter of the interior of the cylinder. The action of the hydraulic regulator is as follows. The cylinder should be nearly filled with water, or other heavy inelastic fluid. In case of any irregularity in the force of the wheel, or in the friction of the brake, the tendency will be, either to raise or lower the weight, in either case the weight cannot move, except with a corresponding movement of the piston. In consequence of the inelasticity of the fluid, the piston can move only by the displacement of a portion of the fluid, which must evidently pass between the edge of the piston and the cylinder; and the area of this space being very small, compared to the area of the piston, the motion of the latter must be slow.

giving time to alter the tension of the brake screws before the piston has moved far. It is plain that this arrangement must arrest all violent shocks, but, however violent and irregular they may be, it is evident, that, if the mean force of them is greater in one direction than in the other, the piston must move in the direction of the preponderating force, the resistance to a slow movement being very slight. A small portion of the useful effect of the turbine must be expended in this instrument, probably less, however, than in the rude shocks the brake would be subject to without its use.

"For the purpose of ascertaining the velocity of the wheel, a counter was attached to the top of the vertical shaft, so arranged, that a bell was struck at the end of every fifty revolutions of the wheel.

"To lubricate the friction pulley, and at the same time to keep it cool, water was let on to its surface in four jets, two of which are shown. These jets were supplied from a large cistern, in the attic of the neighbouring cotton mill, kept full, during the working hours of the mill, by force pumps. The quantity of water discharged by the four jets was, by a mean of two trials, 0.0288 cubic feet per second.

"In many of the experiments with heavy weights, and consequently slow velocities, oil was used to lubricate the brake, the water, during the experiment, being shut off. It is found, that, with a small quantity of oil, the friction between the brake and the pulley is much greater than when the usual quantity of water is applied; consequently, the requisite tension of the brake screws is much less

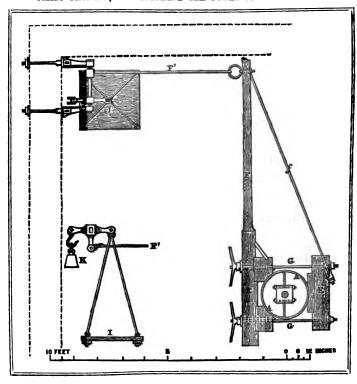

with the oil, as a lubricator, than with water. This may not be the whole cause of the phenomenon, but, whatever it may be, the ease of regulating in slow velocities is incomparably greater with oil as a lubricator, than with water applied in a quantity sufficient to keep the pulley cool. The oil was allowed to flow on in two fine continuous streams; it did not, however, prevent the pulley from becoming heated sufficiently to decompose the oil, after running some time, which was distinctly indicated by the smoke and peculiar odour. When these indications became very apparent, the experiment was stopped. and water let on by the jets, until the pulley was cooled. As the pulley became heated, the brake screws required to be gradually slackened. Water. linseed oil, and resin oil, were each used for lubrication."

Fig. 46 is a representation of a brake used by Professor Thomson, at Crawford and Lindsay's mill, to determine the power of a turbine put up there, by Mr. Gardner, of Armagh. One of the common causes of the swinging or vibratory jumps of the arms r, in Figs. 44, 45, and 46 is, that very often the friction pulley, or drum A, A, must be made in two parts, so as to be fixed to its place on the shaft. This fixing is liable to give an oval shape, and causes an irregular action with the clamps r, r. en gives greater regularity of motion than water, but without the use of the latter abundantly, the friction pulley would usually get too much heated. The following calculations from practical operations will point out pretty clearly the use of the brake, and the manner

of determining the useful effect in the tables of experiments, by Francis and Thomson, pp. 383 and 392:—

FIG. 46.

FRICTION BRAKE, USED AT CRAWFORD AND LINDSAY'S MILL, BY PROFESSOR
JAMES THOMSON, TO DETERMINE THE FOWER OF THE TURBINE.

Length of the brake, I, Fig. 45, adjusted . . . 9.745 feet. Effective length of vertical arm l 4.5 ,, Effective length of horizontal arm l' . . . 5.0 ,,

The effective length of the brake was therefore $\frac{9.745 \times 5}{4.5} = 2 \times 10.827778$ feet; and the circumference of a circle of this radius = $10.827778 \times 3.14159 = 68.0329$ feet.

In the first experiment on the Tremont turbine,

page 393, the number of revolutions of the wheel per second was .89374, and the weight in the scale 1443:34 lbs. The useful effect of the brake was therefore in foot-pounds per second 68.0329 x $\cdot 89374 \times 1443 \cdot 34 = 87680 \cdot 3$ lbs. raised one foot per second. The quantity of water which passed the gauge-weir in cubic feet per second was 139.4206, and the total fall acting on the wheel 12.864 feet; therefore, the total power of the water acting on the wheel was $12.864 \times 139.4206 \times 62.375 = 111870$ feetpounds per second, 62.375 being taken as the weight in lbs. of a cubic foot of water at 32° Fahrenheit. The ratio of the useful effect, at the given velocity of the wheel (viz. 450 revolutions in 503.5 seconds), to the power expended, is therefore $\frac{87680.3}{111870} = .784$, or about 781 per cent. The effect in the experiments generally appears to have been a maximum, when the velocity of the interior circumference of the wheel was about 66 per cent. of the velocity due to the fall; and this was about half of the maximum velocity, which was 1.333 times that due to the fall alone, when the turbine was doing no work.

In Thomson's brake for determining the useful effect of the vortex turbine, erected from his designs at Ballysillan, Ireland, L=4 ft. 2 in., and the circumference of a circle that would be described by the arm $3\cdot14159\times8$ feet 4 inches. $=26\cdot18$ feet. In the first experiment, taken from the tabulated results, page 383, we get $26\cdot18$, the circumference multiplied by $46\cdot31$, the weight in lbs., and the product by $323\cdot3$, the number of revolutions per minute, equal

to 391,967 foot-pounds, for the effect transmitted from the turbine or work done. We have also 354.4, the number of cubic feet of water passed to the wheel per minute, multiplied by 62:37, the weight of a cubic foot of water in lbs., multiplied by 23.73 feet, the available fall, equal to 524,526 foot-pounds: 391,967 therefore $\frac{331,301}{524,526} = .747$ is the useful effect, that in the table being 7481, which probably arose from taking a different weight per cubic foot for the water. Of course the difference is immaterial. The drum attached to the vortex wheel shaft for fixing the brake to, was in two parts, bolted together, and firmly enclosing the shaft. It was of cast-iron, 20 inches diameter, and 8 inches wide; the shaft to which it was attached was 2% inches diameter. arm of the brake was $5'\cdot 4'' \times 6'' \times 4'' \frac{1}{4}$, of timber, and extending 1 foot 2 inches beyond the centre of the shaft and drum. The clamping pieces were about 2 feet 5 inches long externally.

For overshot wheels the ratio of the power to the effect may be taken as 3 to 2, and therefore the effective horse-power, — taking 33,000 foot-pounds per minute as a standard, — will be 49,500 lbs. of water falling one foot in one minute. The maximum effect varies with the construction of the wheel. Smeaton found it .76 times the theoretical power; Weisbach .78 times for the wheel of a Stamp Mill at Frieberg, which was 23 feet high, 3 feet wide, carrying 48 buckets.* To find the effective horse-

^{*} Some valuable experiments on the power of water wheels are given by Rennie, in Weale's Quarterly Papers of Engineering, vol. vi. They however require reduction.

power, the theoretical horse-power must be here divided by the coefficient of effect '76 or '78, which will give 43,600 foot-pounds, or 43,300 foot-pounds per minute. The following experimental results from a model wheel are by Smeaton.

TABLE containing the Result of Sixteen Experiments, on a Model Overshot Wheel, by Smeaton.

In this table the effective power of the water must be reckoned upon the whole descent, because it must be raised that height, in order to be in a condition of producing the same effect a second time.

The ratios between the powers so estimated, and the effects at the maximum, deduced from the several sets of experiments, are exhibited at one view, in column 9, of Table II.; and from hence it appears, that those ratios differ from that of 10 to 7.6 to that of 10 to 5.2, that is, nearly from 4 to 3 to 4 to 2. In those experiments where the heads of water and quantities expended are least, the proportion is nearly as 4 to 3, but where the heads and quantities are greatest, it approaches nearer to that of 4 to 2; and by a medium of the whole, the ratio is that of 3 to 2, nearly. We have seen before, in our observations upon the effects of undershot wheels, that the general ratio of the power to the effect, when greatest, was 3 to 1; the effect, therefore, of overshot wheels, under the same circumstances of quantity and fall, is at a medium double to that of the undershot; and, as a consequence thereof, that non-elastic bodies, when acting by their impulse or collision, communicate only a part of their original power; the other part being spent in changing their figure, in consequence of the stroke.

The powers of water, computed from the height of the wheel only, compared with the effects as in column 10, appear to observe a more constant ratio: for, if we take the medium of each class, which is set down in column 11, we shall find the extremes to differ no more than from the ratio of 10 to 8.1 to that of 10 to 8.5; and as the second term of the ratio gradually increases from 8.1 to 8.5, by an increase of head from 3 inches to 11, the excess of 8.5 above 8.1 is to be imputed to the superior impulse of the water

at the head of 11 inches, above that of 3 inches: so that if we reduce 8·1 to 8, on account of the impulse of the 3-inch head, we shall have the ratio of the power, computed upon the height of the wheel only, to the effect at a maximum, as 10 to 8 or as 5 to 4, nearly; and from the equality of the ratio between power and effect subsisting, where the constructions are similar, we must infer, that the effects, as well as the powers, are as the quantities of water and perpendicular heights, multiplied together respectively.

FOR BREAST WHEELS, the ratio of the theoretical power to the effective power must vary considerably, the mean value being about 1 to 5 and, therefore, the effective horse-power would be 66,000 foot-pounds in one minute. Morin gives an efficiency of from 52 to 7. Egen, with a wheel 23 feet in diameter, 4½ feet wide, having 69 ventilated buckets, very well constructed, found at best an efficiency of only 52, under ordinary circumstances 48, the mean amount being 5. Very wide wheels give a larger effect, sometimes as high as 7; but a great deal depends on the manner of bringing on the water and the construction of the wheel and buckets.

FOR UNDERSHOT WHEELS the mean effect may be taken at one-third or ·33, or 100,000 foot-pounds in one minute for an effective horse's power; a maximum effect of ·5 is sometimes approached, and a minimum of ·26 or less. The following results, obtained from a model, are given by Smeaton. The virtual or effective head is here termed the theoretical head due to the velocity of the wheel, at the circumference, which was 75 inches girth.

Smeaton derived the following "maxims" from the foregoing experiments. Their truth, independent of any experiment, will be apparent:—

- I.—That the virtual or effective head being the same, the effect will be nearly as the quantity of water expended.
- II.—That the expense of water being the same, the effect will be nearly as the height of the virtual or effective head.
- III.—That the quantity of water expended being the same, the effect is nearly as the square of the velocity.
- IV.—The aperture being the same, the effect will be nearly as the cube of the velocity of the water.

For turbines or horizontal wheels, a useful effect of two-thirds or .67 may be assumed, or 49,500 foot-pounds in a minute for a horse-power, and the efficiency varies from .5 to .8, or less.* Poncelet's turbine gives an efficiency of .5 to .6. Floating wheels .38, impact wheels from .16 to .4, and Barker's mill from .16 to .35. We believe that the efficiency of the turbine has been too often overestimated, and that the great advantage of this wheel, as a medium of power, is derived from its capability of employment for all falls, whether large or small, without any considerable loss of effect. In Ireland, Mr. Gardner, of Armagh, was amongst the first, if not the first, to apply this wheel to practical purposes; and Professor Thomson has, in his

* In our first edition we gave an efficiency of 821, on the authority of a paper by Dr. Robinson, Armagh, in the Proceedings of the Royal Irish Academy, vol. iv., p. 214. On again glancing over this paper, we believe there are mistakes, which vitiate the results there given; first, in the formula for calculating the discharge over the weir, and next, in the formula for finding the effect of the brake. Francis gives an efficiency of 88, p. 3, his book.

vortex wheels, produced, we believe, the highest efficiencies which have yet been obtained in practice. In the experiments on the Ballysillan wheel, higher efficiencies would probably have been attained with a supply pipe of larger diameter. It will be seen from the remarks, at pp. 171 and 172, and the tables, at pp. 152 and 191, that quite apart from bends, &c., a loss of mechanical power always results from the passage through orifices and pipes; and that it is necessary to take this loss into account, before the head acting on the wheel can be accurately used to determine its effective power. The table, next page, contains the experiments on the Ballysillan turbine.

The following remarks on the vortex turbine, read at the meeting of the British Association at Belfast, in 1852, are also by Professor Thomson:—

"Numberless are the varieties, both of principle and of construction, in the mechanisms by which motive power may be obtained from falls of water. The chief modes of action of the water are, however, reducible to three, as follows: -First, the water may act directly by its weight on a part of the mechanism which descends while loaded with water, and ascends while free from load. The most prominent example of the application of this mode is afforded by the ordinary bucket water wheel. Secondly, the water may act by fluid pressure, and drive before it some yielding part of a vessel by which it is confined. This is the mode in which the water acts in the water pressure engine, analogous to the ordinary high-pressure steam-engine. Thirdly, the water, having been brought to its place of action subject to the pressure

TABULATED STATEMENT of Experiments made on March 20th, 1884, by Professor James Thomson, O.E., Queen's College, Belfast; on the Vortex Wheel at Ballysillan, to determine its efficiency. The Radius of the Friction Brake was 4 feet 3 inches. The corresponding Circumference is 20:18 feet. In this Table, the quantity of Water passing over the Weir is calculated by means of M.M. Poncelet and Lesbros' Conficients for Notches

Total Height of Fall = 24 feet, Standard quantity of Water = 420 cubic feet per minute. Calculated speed 2025 revolutions per minute. Effective Standard Power remained as a medicine of the per minute. The standard proper section 1625 Horse Power. Supply pipe, 21 inch bore. Diameter of Wheel, I foot 84 inches a manufer of the standard quantity of water for REMARKS.—It is no be observed, that as the experiments happened to be made in dry water the stream in none of them supplied the standard quantity of water for Abstract of the Data and Calculations according to which the Vortex Wheel was designed.

which the wheel was more particularly adapted. Even with the diminished quantity of water, the efficiencies experimentally found were very high. It is also to be observed, that in some of the experiments the resistance to the wheel was purposely made less than what was most suitable for the water supply. The wheel thus ran considerably too has in those experiments, and consequently the efficiencies in them came to be not so high as in the others that were more properly arranged. Also, from information received after the time of the experiments, it appeared that during the experiments the Joint Rings of the Vortex were not screwed properly close to the rings of the Water Whosel; and that on their being afterwards screwed, the power of the wheel was sensibly increased. It is therefore probable that still higher efficiencies are statishable than those above or probable that still higher efficiencies are

Digitized by Google

due to the height of fall, may be allowed to issue through small orifices with a high velocity, its inertia being one of the forces essentially involved in the communication of the power to the moving part of Throughout the general class of the mechanism. water wheels called turbines, which is of wide extent, the water acts according to some of the variations of which this third mode is susceptible. In our own country, and more especially on the Continent, turbines have attracted much attention, and many forms of them have been made known by published descriptions. The subject of the present communication is a new water wheel, which belongs to the same general class, and which has recently been invented and brought successfully into use by the author.

"In this machine the moving wheel is placed within a chamber of a nearly circular form. The water is injected into the chamber tangentially at the circumference, and thus it receives a rapid motion of rotation. Retaining this motion it passes onwards towards the centre, where alone it is free to make its exit. The wheel, which is placed within the chamber, and which almost entirely fills it, is divided by thin partitions into a great number of radiating passages. Through these passages the water must flow on its course towards the centre; and in doing so it imparts its own rotatory motion to the wheel. The whirlpool of water acting within the wheel chamber, being one principal feature of this turbine, leads to the name Vortex as a suitable designation for the machine as a whole.

"The vortex admits of several modes of construction, but the two principal forms are the one adapted for high falls and the one for low falls. The former may be called the High-pressure Vortex, and the latter the Low-pressure Vortex. Examples of these two kinds are in operation at two mills near Belfast.

"The height of the fall for the first vortex is about 37 feet, and the standard or medium quantity of water, for which the dimensions of the various parts of the wheel and case are calculated, is 540 cubic feet per minute. With this fall and water-supply the estimated power is 28 horse-power, the efficiency being taken at 75 per cent. The proper speed of the wheel, calculated in accordance with its diameter and the velocity of the water entering its chamber, is 355 revolutions per minute. The diameter of the wheel is $22\frac{5}{8}$ inches, and the extreme diameter of the case is 4 feet 8 inches.

"In the second vortex, the fall being taken at 7 feet, the calculated quantity of water admitted, at the standard opening of the guide-blades, is 2,460 cubic feet per minute. Then, the efficiency of the wheel being taken at 75 per cent., its power will be 24 horse-power. Also, the speed at which the wheel is calculated to revolve is 48 revolutions per minute.

"The two examples which have now been described of vortex water wheels, adapted for very distinct circumstances, will serve to indicate the principal features in the structural arrangements of these new machines in general. Respecting their principles of action some further explanations will next be given. In these machines the velocity of the circumference is made the same as the velocity of the entering water, and thus there is no impact between the water and the

wheel; but, on the contrary, the water enters the radiating conduits of the wheel gently, that is to say, with scarcely any motion in relation to their mouths. In order to attain the equalization of these velocities, it is necessary that the circumference of the wheel should move with the velocity which a heavy body would attain, in falling through a vertical space equal to half the vertical fall of the water, or in other words, with the velocity due to half the fall; and that the orifices through which the water is injected into the wheelchamber should be conjointly of such area that when all the water required is flowing through them, it also may have a velocity due to half the fall. Thus one-half only of the fall is employed in producing velocity in the water; and, therefore, the other half still remains acting on the water within the wheel-chamber at the circumference of the wheel, in the condition of fluid pressure. Now, with the velocity already assigned to the wheel, it is found that this fluid pressure is exactly that which is requisite to overcome the centrifugal force of the water in the wheel, and to bring the water to a state of rest at its exit: the mechanical work due to both halves of the fall being transferred to the wheel during the combined action of the moving water and the moving wheel. In the foregoing statements, the effects of fluid friction, and of some other modifying influences, are, for simplicity, left out of consideration; but in the practical application of the principle, the skill and judgment of the designer must be exercised in taking all such elements, as far as possible, into account. To aid in this, some practical rules, to which the author as yet closely adheres,

were made out by him previously to the date of his patent. These are to be found in the specification of the patent, published in the Mechanics' Magazine for January 18 and January 25, 1851 (London).

"In respect to the numerous modifications of construction and arrangement which are admissible in the vortex, while the leading principles of action are retained, it may be sufficient here merely to advert,—first, to the use of straight instead of curved radiating passages in the wheel; secondly, to the employment, for simplicity, of invariable entrance orifices, or of fixed instead of moveable guide-blades; and lastly, to the placing of the wheel at any height, less than about thirty feet, above the water in the tail-race, combined with the employment of suction pipes descending from the central discharge orifices, and terminating in the water of the tail-race, so as to render available the part of the fall below the wheel.

"In relation to the action of turbines in general, the chief and most commonly recognized conditions, of which the accomplishment is to be aimed at, are that the water should flow through the whole machine with the least possible resistance, and that it should enter the moving wheel without shock, and be discharged from it with only a very inconsiderable velocity. The vortex is in a remarkable degree adapted for the fulfilment of these conditions. The water moving centripetally (instead of centrifugally, which is more usual in turbines), enters at the period of its greatest velocity (that is, just after passing the injection orifices) into the most rapidly moving part of the wheel, the circumference; and, at the period

when it ought to be as far as possible deprived of velocity, it passes away by the central part of the wheel, the part which has the least motion. Thus, in each case, that of the entrance and that of the discharge, there is an accordance between the velocities of the moving mechanism and the proper velocities of the water.

"The principle of injection from without inwards, adopted in the vortex, affords another important advantage in comparison with turbines having the contrary motion of the water; as it allows ample room, in the space outside of the wheel, for large and well-formed injection channels, in which the water can be made very gradually and regularly to converge to the most contracted parts, where it is to have its greatest velocity. It is as a concomitant also of the same principle, that the very simple and advantageous mode of regulating the power of the wheel, by the moveable guide-blades already described, can be introduced. This mode, it is to be observed, while giving great variation to the areas of the entrance orifices, retains at all times very suitable forms for the converging water channels.

"Another adaptation in the vortex is to be remarked as being highly beneficial, that, namely, according to which, by the balancing of the contrary fluid pressures due to half the head of water and to the centrifugal force of the water in the wheel, combined with the pressure due to the ejection of the water backwards from the inner ends of the vanes of the wheel when they are curved, only one-half of the work due to the fall is spent in communicating vis viva to the water,

to be afterwards taken from it during its passage through the wheel; the remainder of the work being communicated through the fluid pressure to the wheel, without any intermediate generation of vis viva. Thus the velocity of the water, where it moves fastest in the machine, is kept comparatively low; not exceeding that due to half the height of the fall, while in other turbines the water usually requires to act at much higher velocities. In many of them it attains at two successive times the velocity due to the whole fall. The much smaller amount of action, or agitation, with which the water in the vortex performs its work, causes a material saving of power by diminishing the loss necessarily occasioned by fluid friction.

"In the vortex, further, a very favourable influence on the regularity of the motion proceeds from the centrifugal force of the water, which, on any increase of the velocity of the wheel, increases, and so checks the water supply; and on any diminution of the velocity of the wheel, diminishes, and so admits the water more freely; thus counteracting, in a great degree, the irregularities of speed arising from variations in the work to be performed. When the work is subject to great variations, as for instance in sawmills, in bleaching works, or in forges, great inconvenience often arises with the ordinary bucket waterwheels and with turbines which discharge at the circumference, from their running too quickly when any considerable diminution occurs in the resistance to their motion.

""The first vortex which was constructed on the

large scale was made in Glasgow, to drive a new beetling-mill of Messrs. C. Hunter and Co., of Dunadry, in County Antrim. It was the only one in action at the time of the meeting of the British Association in Belfast; but the two which have been particularly described in the present article, and one for an unusually high fall, 100 feet, have since been completed, and brought into operation. There are also several others in progress; of which it may be sufficient to particularize one of great dimensions and power, for a new flax-mill at Ballyshannon in the West of Ireland. It is calculated for working at 150 horse-power, on a fall of 14 feet, and it is to be impelled by the water of the River Erne. This great river has an ample reservoir in the Lough of the same name; so that the water of wet weather is long retained, and continues to supply the river abundantly even in the dryest weather. The lake has also the effect of causing the floods to be of long duration, and the vortex will consequently be, through a considerable part of the year, and for long periods at a time, deeply submerged under backwater. The water of the tail-race will frequently be seven feet above its ordinary summer level; but as the water of the head-race will also rise to such a height as to maintain a sufficient difference of levels, the action of the wheel will not be deranged or impeded by the floods. These circumstances have had a material influence in leading to the adoption in the present case of this new wheel in preference to the old breast or undershot wheels."

. The next tables have been arranged by us from

Mr. Francis' valuable experiments. They show the ratio of the effect to the power in two wheels, the first a centre-vent wheel, erected at the Boott Cotton Mills, and the second a turbine, erected at the Tremont Mills, Lowell, Massachusetts.

The maximum effect .794 was obtained from the Tremont turbine experiments, when the velocity of the interior circumference of the wheel was to that due to the whole fall as .63 to 1; and an effect of 78 per cent. was obtained when these velocities were as ·51 to 1. In the Boott centre-vent wheel the maximum effect .797 was obtained when the velocity of the exterior circumference was to that due to the fall as .64 to 1; and a like effect was produced when this ratio was '708 to 1. Indeed, between these ratios the useful effect was nearly the same; an effect of .78 to .79 was obtained for all such ratios between limits of .59 and .71 to 1, averaging a ratio of .65 to 1. If a turbine have a variable fall, say from 2 to 1, and be of sufficient capacity to give the required power always, the dimensions should be determined from the lesser fall, and if correctly so determined, it will not have sufficient velocity for the greater fall. When the fall is greatest the quantity in the same place is generally least, giving thereby a lessened effect when most is required. For such cases two turbines may be used with advantage.

TABLE showing the Results of Experiments upon a Model of a Centre-vent Water Wheel, and also upon a Centre-vent Water Wheel at the Boott Cotton Mills, Lowell, Massachusetta, arranged from Mr. Francis' valuable Experiments. Diameter of Wheel to the outside of the Buckets, about 93 feet. Depths of External Anide Curve about '15 foot. External height of Wheel about 15 feet. Number of Buckets, 40. Mean height of the Orifices between the Guidea, 1 foot. Diameter of Supply Pips, 3 feet. The first Seven Experiments were made on a Model, the Exterior Diameter of the Wheel being 21 inches, Interior Diameter 19½ inches, height between the Crowns 2½ inches, and the number of Buckets 35. The Construction of the Wheel is shown in Mr. Francis' Book, and all necessary Details. The general principle of the Centre-vent Wheel of Francis' and Thomson's Voriex Wheel appears to be the same; the Guide Blades being fewer in the latter, and capable of adjustment.

Numbers of the Experiments.	Falls acting on the Wheels.	Depth on the Weirs in feet,	Cubic fact of Water acting on the Wheel per second.	Number of pounds avoir- dupois, if raised one foot per second.	Revolutions of the Wheel per second.	Weight in the scale in pounds avoirdupois.	Ratios of the ef- fect to the power, calculated by means of Prony's Brake.	Velocity due to the fall acting on the Wheel, in feet per second.	Velocity of the outside circum-ference of the Wheel, in feet per second.

TABLE showing the Results of Experiments upon the Turbine at Irrmont Mile, Lowell, Massachusetts, arranged from Mr. Francis' valuable Experiments. Diameter, measured to the Exterior Circumference of Crowns of the Wheel, 8383 feet. Height of Buckets from top of the Diec to the bottom of the Garniture, If feet. Number of Buckets, 44. Width, of the Buckets & Joot, nearly. Width of Guide Curves, 28 feet, nearly. Number of Ditto, 88. A Double Weisr with 4 end constructions and 1698 feet long, used for gauging the Water the Crest being 65 feet above the floor of the Wheel Pit. The Falls show the difference of heads in the Forebay and Wheel Pit. For further details, see Francis' Lovell Hydraulic Experiments, pp. 1 to 48. The supply pipe is fully a quadrant, and varies from 6 to 9 feet in diameter.

THE HYDRAULIC RAM has been applied with advantage in raising water to a considerable height by the momentum of a larger quantity at a lower level. The shock of the valves, and vibration of the machine, require heavy and strong setting, and considerable strength in all the parts. This limits its application, and prevents its use for raising large quantities of water. The work done by the ram, in over one thousand experiments by Eytelwein, did not exceed in any of them 1480 lbs. raised one foot in one minute; and in France, the ram put up by the younger Montgolfier, said to be the largest constructed, raised only 7400 lbs. one foot high per minute, and had a useful effect, it is reported, of .65. This ram was put up at Mello, near Clermont-sur-Oise. Its dimensions were-

Length of the body pipe	or inj	ection	pipe	108 feet.
Diameter		.•	,	4.3 inches.
Weight of body pipe .		•		8190 lbs.
Weight of head		•	,	44 0 lbs.
Contents of air-chamber	•	•		11 gallons

This ram worked under a head of 37 feet, discharging in use 31½ gallons each minute, and raising 3.85 gallons a height of 195 feet.

The largest ram employed by Eytelwein in his experiments had the following dimensions—

Length of the body pipe or	r	injec	tion	pipe	43 feet 9 inches.
Diameter of ditto .	•		•	•	0 feet 21 inches.
Contents of air-chamber	•			•	1.94 gallons.
Area of tail or escape valve	٠.	•	•	•	3.74 square inches;

and his experiments led to the following practical formula by D'Aubuisson—

$$\frac{dh'}{dh} = 1.42 - .28\sqrt{\frac{h'}{h}}:$$

in which D is the water used per minute in gallons, d the quantity raised in gallons, h the head used, and h' the lift of the quantity d. By a slight reduction we get

$$dh' = 1.42 \text{ D} (h - .28 \sqrt{hh'})$$

for the effect produced, which is reduced nearly onesixth for practical application, giving the formula

$$dh' \equiv 1.2 \text{ D} (h - \cdot 2\sqrt{h h'})$$

for the work done.

Eytelwein recommends, that the length of the body pipe should not be less than three-fourths of the height to which the water is to be raised; its diameter in inches equal $58\sqrt{D}$; the diameter of the rising pipe $3\sqrt{D}$; and the contents of the airchamber equal to that of the rising pipe.

The following table gives the result of experiments made by Montgolfier and his son:—

TABLE OF EXPERIMENTAL RESULTS-HYDRAULIC RAW.

Latterly, the Messrs. Easton and Amos have patented improvements in this machine, and have raised water to a height of 330 feet. The injection pipe is laid by them at an inclination of about one in four for high falls, and varies down to one in eighteen for smaller falls. The quantities raised in their practice vary up to six gallons per minute.

WATER PRESSURE ENGINES give a useful effect varying up to 70 per cent. for the best constructed. An immense amount of mechanical skill and invention has been brought to bear on their construction,

and in Weisbach's book. a useful effect of 83 per cent. has been calculated; this is, however, a result seldom obtained in practice, where two-thirds, or 66 per cent., is nearer to the general efficiency. Jordan got a maximum efficiency of '66 from one of the Clausthal engines, making four strokes per minute, and '71 making three strokes per minute. These results were for the combined engine and pumps, from which it was calculated that the efficiency of the engine alone, was in the first case '83, and in the second '85. It would be a great mistake to calculate on such high efficiencies.

CORN MILLS will grind about a bushel of corn per horse-power per hour, but much depends on the state of the stones and of the grain. The value of the work done in an hour being once known, the value of the standard horse-power can be determined accordingly.

TABLE III.—Square Roots for finding the effects of the Velocity of
Approach when the Orifice is small in proportion to the Head.
Also for finding the Increase in the Discharge from an Increase of Head. (See p. 101.)

TABLE VI.—The Discharge over Weirs or Notches of one foot in length, in Cubic feet per minute.

Depths 33 inches to 72 inches. Coefficients .606 to .518.

LESSER COEFFICIENTS.

The Formulæ at the heads of the Columns give the Value of the Discharge, D, in Cubic feet per minute, whence l, the length of the Weir, is taken in feet, and the head, h, in inches. For $l\sqrt{h^2}$ we may substitute l $h\sqrt{h}$ retaining the same standards.

TABLE VIII.—For finding the Mean Velocities of Water flowing in Pipes, Drains, Streams, and Rivers.

The hydraulic mean depth is found for all channels, by dividing the wetted perimeter into the area.

Hydraulic mean depths 6 inches to 10 inches. Falls per mile 1 inch to 12 feet.

	inches	alle in feet and s, and the inclinations.	** H	ydraulic me and velocit	an depths," les in inches	or "mean re per second.	dli,"

TABLE XI.—Mean relative Dimensions of equally Discharging Trapezoidal Channels, with Side Slopes varying from 0 to 1, up to 2 to 1.

Half sum of the top and bottom is the mean width. The ratio of the slope, multiplied by the depth, subtracted from the mean width, will give the bottom; and if added, will give the top.

Table XII. gives the discharge in cubic feet per minute from the primary channel, 70 wide, and the corresponding depths taken in feet. For lesser or greater channels and discharges, see Rules, pp. 227, 229, 232, 249, and 252.

TABLE XII.—Discharges from the Primary Channel in the first column of Table XI.

If the dimensions of the primary channel be in inches, divide the discharges in this table by 500; if in yards, multiply by 15.6; if in quarters, multiply by 32; and if in fathoms, by 88.2, &c.: see pp. 233, 234. The final figures in the discharges may be rejected when they do not exceed one-half per cent., or 0.5 in 100. See pages 226 to 234.

TABLE XIII.—The Square Roots of the fifth powers of numbers for finding the Diameter of a Pipe, or dimensions of a Channel from the Discharge, or the Reverse; showing the relative Discharging Powers of pipes of different Diameters, and of any similar Channels whatever, closed or open. See pages 31, 230, 233, etc.

If d be the diameter of a pipe, in feet, and D the discharge in cubic feet per minute, then for long straight pipes we shall have for velocities of nearly 3 feet per second, D = 2400 $(d^5 s)^3$, and $d = 0.044 \left(\frac{D^2}{s}\right)^{\frac{1}{3}}$; or if D be the discharge per second, D = 40 $(d^5 s)^3$,

and $d = .228 \left(\frac{D^2}{s}\right)^{\frac{1}{2}}$. See pages 190 to 224, and pages 42 and 48.

TABLE XIV.—Weights and Measures, English and French, with their relative values.

MEASURES OF LENGTH.

12 inches	•••	 . 1 foot.
7.92 inches	•••	 . 1 link.
8 feet	• • • •	 . 1 yard.
$5\frac{1}{2}$ yards = $16\frac{1}{2}$ f	eet	 . 1 pole or perch.
100 links = 22	yards	 . 1 chain = 4 perches.
40 perches = 220	yards	 . 1 furlong.
8 furlongs=1760	yards	 . 1 mile.
6 feet	•••	 . 1 fathom.
120 fathoms	• •••	 . 1 cable's length.
1 Nautical mile		 . 6082·7 feet.
69·12 miles		 . 1 Geographical deg.
3 miles	•••	 . 1 league.

The Irish perch is 21 feet, or seven yards. Three inches make a palm; 4 inches a hand; 5 feet a pace. In cloth measure $2\frac{1}{4}$ inches = 1 nail; 4 nails = 1 quarter; 4 quarters 1 yard. 11 Irish miles = 14 English.

MEASURES OF SURFACE.

144 square inches		•••		1 square foot.
62.7264 ,,	•••	•••		1 square link.
9 square feet	•••	•••		1 square yard.
301 square yards	= 2723	square	feet	1 square perch.
10,000 square links	=4,856	, ,,	•••	1 square chain.
10 square chains	= 160	square p	erches	1 acre.
1 rood	= 210	square y	ards	40 perches.
4 roods	=4,840	,,	•••	1 acre.
640 acres	=3,097,	600 ,,	•••	1 square mile.

The Irish perch is 49 square yards, or 441 square feet; 1 Irish acre=1a. 2r. 19·17p. statute; and 1 statute acre=0a. 2r. 18·77p. Irish. The Irish acre is to the English acre as 196 is to 121. 100 square feet, is a square of roofing, slating, or flooring. The Cunningham acre is = 1a. 1r. 6·61p. English; and 1 English acre is = 0a 3r. 8·904p. Cunningham measure.

CUBIC MEASURES, AND MEASURES OF CAPACITY AND WEIGHT.

1728 cubic inches		•••	•••	1 cubic foot.
27 cubic feet				1 cubic yard.
$16\frac{1}{2} \times 1\frac{1}{2} \times 1 =$	24·75 c	ubic feet	•••	1 perch of masonry
$16\frac{1}{2} \times 16\frac{1}{2} \times 1\frac{1}{6} =$	806 c	ubic feet	•••	1 rod of brickwork,
$21 \times 1\frac{1}{2} \times 1 =$	80 <u>1</u> c	ubic feet	•••	1 Irish perch of masonry

The standard gallon, imperial measure, contains 10 lbs. avoirdupois, of distilled water at 62° Fahrenheit, the barometer standing at 30 inches.

6.232 gallons	•••	•••	1 cubic foot
8.665 cubic inches	•••	•••	1 gill.
4 gills 34.659 cubic inch	es		1 pint.
2 pints 69.318 cubic inch	es	•••	1 quart.
2 quarts 188.637 cubic in	ches	•••	1 pottle.
2 pottles 277.274 cubic in	ches	•••	1 gallon.
2 gallons 554.548 cubic in	ches	•••	1 peck.
4 pecks 2218 191 cubic in	ches	•••	1 bushel.

The old Irish gallon contained 217.6 cubic inches, nearly, and 1 Irish gallon is therefore = .7850 imperial gallon. The Irish barrel of lime still measures 40 Irish gallons, or 31.321 imperial gallons, or 4 bushels, very nearly. It is measured by a cylindrical measure 12 inches high, and about $21\frac{1}{2}$ inches in diameter, containing half the Irish barrel. In the old English liquid measures for ale and beer, 36 gallons = 1 barrel = 36 gallons, $3\frac{1}{2}$ quarts, imperial measure, nearly.

For old dry measures, 32 bushels = 1 chaldron = 31 bushels, 1 pint, imperial measure, nearly.

And 36 bushels of coal = 1 chaldron of coal = 34 bushels 3 pecks, and 1 gallon, imperial measure. The Irish barrel of wheat is 20 stone; barley 16 stone; oats 14 stone.

TROY WEIGHT.

24 grains	•••	•••	•••	1 pennyweight.
20 pennyweights	•••	•••	•••	1 ounce
12 ounces	•••	•••	•••	1 pound.

One pound Troy = 22.816 cubic inches of distilled water, barometer 80 inches; thermometer 62° ,

ORIFICES, WEIRS, PIPES, AND RIVER

VERS	453
(TXIV	1 315 1TV)
CALI	

APOTHECARY'S WEIGHT.

20 Troy grain	as	•••	•••	•••	1 scruple.
8 scruples	•••	•••	•••	•••	1 drachm.
8 drachms	•••	•••	•••	•••	1 ounce.
12 ounces	• 6 •	•••	•••	•••	1 pound.

The ounce weighs 480 grains, and the pound 5760 grains, both in Troy and Apothecary's weight.

AVOIRDUPOIS OR COMMERCIAL WEIGHT.

One pound Avoirdupois = 27.7274 cubic inches, when the barometer stands at 80 inches, and Fahrenheit's thermometer at 62° .

16 drachms	=	437	5 Troy	grains	•••	1 ounce
16 ounces	=	7,000	Troy	grains	•••	1 pound
14 pounds	=	98,000	Troy	grains	•••	1 stone
8 stone	=	112	pounds	•••	•••	1 cwt.
20 cwt.	=	2,240	pounds	•••	•••	1 ton

One pound Troy = .82286 pounds Avoirdupois, and one pound Avoirdupois, is equal to 1.2158 pounds Troy. One ton of water contains about 36 cubic feet, equal to 224 imperial gallons, nearly. Ten pounds of distilled water is equal to one gallon, the Barometer and Thermometer being as above stated.

FRENCH MEASURES AND WEIGHTS COMPARED WITH ENGLISH.

MEASURES OF LENGTH.

1 métre .		3-2808992 feet	1 foot English	•3047945 métre
1 decimétre		·3280899 "	1 inch 1 yard 1 perch, 5½ yds.	·0253995 ,,
1 centimétre.		-0328090 ,,	1 yard	9143835
1 millimétre .		0032809 ,,	1 perch, 5½ yds.	5.0291092 ,,
1 kilométre(or	1000 métr	es)·621383 mile	1 mile	1.60932 kilométre

1000 métres == 100 decamétres == 10 hectométres == 1 kilométre == 3280.849 feet. The métre is the 10,000,000th part of a quadrental arc of the meridian or 39.3708 inches English.

MEASURES OF SURFACE

1 centiare (one squar métre)	e } 10-7648 sq. ft.	119.6033 sq. yds.	1 are 1 deciare
1 deciare 1 are	107·6430 " 1076·430 "	1.1960 "	{ 1 centiare or sq. metre.

100 ares = 10 deciares = 1 hectare = 2.471143 English acres, and 17 hectares are nearly equal to 42 English acres.

The old Paris foot is equal 1-06678 English feet; the French inch = 1-06578 English inches; the French line -08882 of an English inch; the toise is equal to 6 French feet = 76·736 English inches = 6·39468 feet. The perches is 18 French feet; and the perch royal 22 French feet. The French square foot or inch = 1·13581 English square feet or inches, and the cubic foot or inch = 1·21061 English.

MEASURES OF SOLIDITY AND CAPACITY.

1 millistere 1 centistere	0353166 353166		1 millilitre	•0610279	Eng. cub.
1 decisters	8-59166	99 99	1 centilitre	•610279	,
1 stere (one cul	bic) ar ar ar	77	1 decilitre	6.10279	>9
métre	20.8166	99	1 litre	61-0979	**
1 decastere	358-166	,,	1 decalitre	610-279	,,
1 hectostere	3531.66	"	1 hectolitre	6102.79	"
1 kilostere	85816-6	,,,	1 kilolitre	61027-9	"

The stere and kilolitre are each a cubic metre, and the litre is a cubic decimetre; 50 litres are nearly 11 English gallons, and 1 hectolitre 2.751207 English bushels.

MRASURES OF WEIGHT.

•0648 gramme = 1 grain, and 7000 grains = 1 lb. Avoirdupois.

1 milligramme	••	·015432	grains	1 gramme	• •	15.482 gr	ains
1 centigramme	• •	15482	,,	1 decagramme	• •	·022051	p avoir.
1 decigramme	••	1.5432	,,	1 hectogramme		·2205	,,
1 gramme	••	15·432		1 killogramme	••	2.2046	••

1.01605 tonnes = 1 ton; and 1 tonne = .984206 ton.

A gramme is the weight of a cubic centimetre of water and its maxim, density in vacuo, 1 kilogramme = 2.6795 lbs. Troy = 2.2046 lbs. Avoirdupois. 1 metrical quintal 220.46 lbs. Avoirdupois, and 10 quintals is equal to the weight of a cubic metre of water.
